Recent work by Smith, Andrewes, and Laidlaw is highly suggestive that this may be the true solution of the problem. These workers have succeeded in producing influenza in ferrets and from ferrets to ferrets thereafter by the nasal route, using bacteria-free filtrate from nasal washings from influenza patients. Ferrets were not infected by similar material from non-influenzal persons or from persons who had a cold in the head. Serum from convalescent humans protected other ferrets from infection for several months.

A PLEOMORPHIC VIRUS ?

If influenza is a virus disease, is it not possible to assume that the virus may be of several types, just as the pneumococcus and the meningococcus are of several "types," and that the different clinical forms of disease may depend on which type of virus is the predominant infecting agent, or even that the virus may exhibit mutation from one type to another, or again that there may be several allied viruses in the sense that typhoid and the various paratyphoid bacilli are allied but yet sufficiently different, in that they do not confer cross-immunity the one to the other? This might help to explain the rather anomalous questions of post-influenzal immunity as, for example, the apparent clinical fact that people who had suffered from influenza in 1890 and who were alive in 1918 for the most part escaped infection in that year. In contrast with this we find that annual influenzal attacks are a commonplace. May it not be that this hypothetical virus attacks by preference the mucous membranes or the nervous system, and that at times of epidemics the virus is more deadly, and so damages the mucosae, or so impairs the balance between the sympathetic and parasympathetic nervous systems, or other parts of the central nervous system, that invasion by secondary pathogenic organisms is made easy, and resistance to these invaders is made difficult or impossible by reason of upset and damage to the nervous and metabolic processes which regulate the healthy protective mechanism against bacterial invasion?

It has been suggested by Smith Jelliffe that many of the clinical phenomena of influenza—the headache, the sweats, the pains, the bradycardia, the depression, and the tendency to exudate formation in the lungs and elsewhere—may be explained by a profound disturbance in the balance between the autonomous and sympathetic nervous systems. It seems reasonable. Certainly many cases of post-influenzal bradycardia so marked as to suggest heart-block have been shown by the electrocardiograph to be due merely to vagus over-activity, though in other cases true heart-block and other such disturbances of rhythm as flutter and fibrillation may occur with obvious myocardial damage. May not the apparent connexion between poliomyelitis, cerebro-spinal meningitis and encephalitis, and influenza be explained by the possibility that the one prepares the ground for the invasion by the other, and vice versa; or may not the factor of symbiosis explain some of the secondary invasions and differences in virulence? Hamer has shown that on one occasion when a cerebro-spinal fever epidemic followed closely on an influenzal epidemic the incidence of the cerebro-spinal meningitis was ten times greater among those who had had influenza than the statistical expectation warranted, while Brorström in 1910 emphasized the relation between poliomyelitis and influenza.

TREATMENT AND PROPHYLAXIS

It remains but to say a very few words about treatment. Here I am on difficult ground. The treatment of the attack of influenza is peculiarly the province of the general practitioner; the number of different remedies

that have been extolled shows clearly that there is no specific. All are agreed that early and prolonged rest in bed is all-important, and most of us have our pet prescriptions, usually based on aspirin and caffeine, whereby we hope to relieve the more intolerable of the symptoms; but few of us, I fancy, claim in any way to cure influenza. The prospect of doing good by the use of convalescent serum is attractive but beset with difficulty. We have done a little work in this direction within the hospital, and hope to do more when the opportunity offers. At present it can only be said that research in this direction offers at least a possibility of some day providing a valuable therapeutic agent. The only other question that occurs to me is the possibility of doing good in times of epidemic influenza by wholesale prophylactic vaccination against the secondary invaders. I myself am convinced that therapeutic vaccination when the secondary invasion has occurred is utterly useless, but I feel that the secondary invasion might perhaps be avoided if the individual were protected by a previous course of mixed vaccine against the potential invaders.

THE EPIDEMIOLOGY OF SCARLET FEVER IN A LANDWARD AREA

BY

JOHN RIDDELL, M.B., CH.B., D.P.H.

ASSISTANT MEDICAL OFFICER OF HEALTH, COUNTY OF STIRLING

The recent publication by the Medical Research Council of an *Epidemiological Study of Scarlet Fever in England and Wales since 1900*, by Hilda M. Woods, raises many points of great interest and importance. Perhaps the most striking conclusion to be drawn is that the present low mortality rate is probably only temporary, and that a recurrence of the more malignant type of scarlet fever may be expected. In view of this it would appear wise to concentrate our efforts now on elucidating any factors which might affect the incidence or mortality of the disease, in order that we may be prepared for, and, if possible, prevent, this future source of anxiety. It is hoped that this study, while making no pretension to be exhaustive, may lead to speculation and possibly further investigation into some unexplored aspects of the subject.

The cases dealt with comprise all the notifications of scarlet fever in the landward area of Stirlingshire during the ten years 1921-30. As mentioned in the Medical Research Council's report,¹ notifications do not, of course, form an infallible basis for statistical conclusions, owing, in a landward area especially, to the number of missed cases and other causes, but in a study such as this the effect of these errors can at most only be slight.

PERIODICITY

In the ten years covered no decision can be reached with regard to the periodicity of the disease in this area, but it would appear to conform to the usual five to seven years. In order not to break up the periods of greatest incidence, each year has been taken as commencing on July 1st and ending on June 30th succeeding. Table I shows a minimum incidence in 1922-3, rising to a maximum in 1925-6, and falling to a minimum again in 1927-8—that is, a period of five years between the two minima.

If the cases are now subdivided into age groups—corresponding roughly to pre-school children, school children, and adults—the interesting fact emerges that there is less annual variation in the incidence among adults, and that there is also a tendency for a "lag"

to occur—that is, the minimum incidence comes a year later, the maximum a year later, and the following minimum two years later, than in the case of children.

TABLE I.—Annual Incidence

	Period Covered											
	Jan. 1921 to June, 1921	July, 1921 to June, 1922	July, 1922 to June, 1923	July, 1923 to June, 1924	July, 1924 to June, 1925	July, 1925 to June, 1926	July, 1926 to June, 1927	July, 1927 to June, 1928	July, 1928 to June, 1929	July, 1929 to June, 1930	July, 1930 to Dec., 1930	
All cases	277	180	149	207	381	449	429	217	260	253	117	
Ages 0 to 4 yrs. 11 mos. ...	51	40	57	93	128	107	52	59	56			
Ages 5 yrs. to 13 yrs. 11 mos. ...	101	84	126	225	268	243	111	156	163			
Ages 14 years and over ...	28	25	24	58	53	79	54	45	39			

TABLE II.—Seasonal Incidence

	Month											
	July	Aug.	Sept.	Oct.	Nov.	Dec.	Jan.	Feb.	Mar.	April	May	June
All cases	153	219	275	342	270	275	322	284	205	202	177	185
Ages 0 to 4 yrs. 11 mos. ...	38	52	73	91	63	65	63	81	45	55	49	55
Ages 5 yrs. to 13 yrs. 11 mos. ...	95	134	172	212	172	189	195	159	104	110	112	105
Ages 14 yrs. and over ...	25	25	30	41	35	62	61	44	56	37	26	24

Taking all cases reported two peaks are evident—one in October and another in January. If, however, the cases are divided into age groups as before, there is found to be a variation. The pre-school children and school children show a maximum incidence in October, with minor peaks in February and January respectively. There is here no evidence of mass infection among the school children due to resuming school at the end of August. The adult group shows only a very slight increase in October, but a maximum incidence in December and January, with another peak in March. The period of maximum liability to infection among adults would thus appear to follow that of children by two to three months. Both annual and seasonal incidence, therefore, vary with age.

It has been shown by the Registrar-General that the maximal seasonal incidence of mortality in scarlet fever appears to be changing from October and November to January, and that "whereas October is the last month of increasing notifications, increase of deaths continues until January, and until May the proportion of deaths remains much higher than that of notifications." Hilda Woods, dealing with London Eastern Hospital cases from 1905 to 1914, points out that there was a greater tendency for deaths to occur in cases arising in April, May, and June. She also shows that the fatality rate declines with age until adolescence is reached, but tends to rise in adults, and that the relative importance of mortality in later life is becoming progressively greater. This was also found by Pope.³ Can later seasonal incidence and increased spring mortality be explained by the fact that the average age of incidence of scarlet fever is becoming progressively greater, possibly due to better housing conditions and earlier and more general segregation of cases?

VARIATION OF INCIDENCE WITH SIZE OF HOUSE

Annual and seasonal incidence do not vary with size of house; total incidence and age and sex incidence do. Table III gives, first, the absolute number of cases in each size of house, then this number stated as a percentage, and then the percentage of the general population resident in each size of house. These latter

percentages are calculated from the 1921 and 1931 census figures. The cases are then divided into two groups according to age—those under 14 years and those 14 years and over. In the case of the children the population at risk is taken as the number of children in the 2,859 houses from which all the cases were drawn, and in the case of the adults the number of adults in those houses. These numbers are taken as samples in the absence of figures relating to the housing and age distribution of the general population.

TABLE III.—Effect of Size of House on Total and Age Incidence

No. of Apartments	All Cases			Cases 0 to 13 Yrs. 11 Mos.			Cases 14 Yrs. and Over		
	No.	%	% Pop.	No.	%	% Pop.	No.	%	% Pop.
I	211	7.3	6.3	197	8.1	6.9	14	3.2	4.9
II	1,508	52.7	45.3	1,341	55.4	57.4	167	38.1	49.2
III	562	19.7	25.1	470	19.0	19.6	102	23.4	21.5
IV	239	8.4	10.1	193	8.0	7.3	46	10.6	8.5
Over IV ...	339	11.9	15.2	231	9.5	8.8	108	24.7	15.9

It is seen from the figures for all cases that the smaller the number of apartments in the house the greater the relative incidence of fever. When we consider the adults alone, however, we see that the reverse is the case, and when we take the children under 14 years we find an intermediate stage. Had it been possible to obtain figures for the age groups 0 to 4 years 11 months and 5 years to 13 years 11 months separately, would this have shown the younger group as causing the increased incidence in the small houses, with the school children an intermediate group? Increased chances of infection and of acquired immunity in the smaller apartment house would suggest that this would be likely.

That earlier infection does occur in the smaller house is shown in Table IV, where the average ages of the cases under 14 years in each size of house are given. In calculating the ages all children in each year group were taken as being concentrated at the centre of the group—for example, all between 3 and 4 years were counted as 3 years 6 months. These findings agree with the results of Halliday in his investigation of measles cases.⁴

TABLE IV.—Size of House, Overcrowding, and Age Incidence

No. of Rooms	I	II	III	IV	Over IV
Average age of cases	6 yrs. 1 mo.	6 yrs. 7 mos.	7 yrs. 1 mo.	7 yrs. 1 mo.	7 yrs. 7 mos.
Persons per apartment					
Cases	3.7	2.3	1.6	1.1	0.8
General pop.	3.2	2.3	1.6	1.2	

The question now arises, Is the earlier age incidence in the small apartment house due to overcrowding? In Table IV are given the persons per apartment in the case of all the notifications, and corresponding figures for the general population, calculated from the 1921 and 1931 census returns. Except in the case of the one-apartment house there is no more overcrowding in the houses in which scarlet fever occurred than in the corresponding houses of the general population.

As regards sex variation (Table V), a larger percentage of the cases among girls under 14 years comes from the smaller type of house than is the case with boys. Assuming that the sex constitution is the same in each size of

house, this would suggest that in the smaller type of house girls are more liable to infection than boys, while the reverse is the case in the larger houses.

TABLE V.—Size of House and Sex Incidence in Children

	No. of Rooms	I	II	III	IV	Over IV
Percentage number of boys		7.8	53.3	20.1	8.0	10.8
Percentage number of girls		8.5	57.2	18.0	7.8	8.5

VARIATION OF INCIDENCE WITH SEX AND AGE

TABLE VI.—Sex and Age Incidence

	Ages	0 to 11 months	1 yr. to 11 mos.	2 yrs. to 11 mos.	3 yrs. to 11 mos.	4 yrs. to 11 mos.	5 yrs. to 11 mos.	6 yrs. to 11 mos.	7 yrs. to 11 mos.	8 yrs. to 11 mos.	9 yrs. to 11 mos.	10 yrs. to 11 mos.	11 yrs. to 11 mos.	12 yrs. to 11 mos.	13 yrs. to 11 mos.	14 yrs. and over	Totals
M.		8	38	72	110	130	145	129	117	83	69	81	44	46	39	186	1,303
F.		17	40	67	114	139	157	163	138	119	111	86	63	64	59	231	1,621

With the exception of the age group 2 years to 2 years 11 months, there is seen to be an excess of female cases throughout. This shows a true increase in susceptibility, because in the general population of this area there is an excess of males over females at all ages under 20, and also in the general population above that. The fact that a larger proportion of girls than boys come from houses with few apartments, and that the age incidence is earlier in these houses, would suggest that the age incidence in girls should be earlier than in boys. Such is not the case, however, as is seen from Table VI, where 56.6 per cent. of the boys are under 7 years, and only 52.1 per cent. of the girls. Also, in the case of boys the age of maximum incidence is in the fifth year, whereas in girls it is in the sixth year. The excess of female cases and the maximum age incidence at 5 to 6 years are the commonly accepted findings.

SUMMARY

1. The periodicity of scarlet fever in this area appears to be one of about five years.
2. Adults have an annual variation in incidence separate from that of children, and following that of children at about one year's interval.
3. While the maximum seasonal incidence in children is in October, with a smaller increase in January and February, the maximum in adults is in December and January, with a following increase in March.
4. The fewer the number of apartments in the house the higher the incidence of fever among children, but the lower among adults.
5. The smaller the house the earlier the average age of infection among children. This does not appear to be due to overcrowding *per se*.
6. Females are more liable to infection with scarlet fever than males, but girls are not affected until a later age than boys, though a larger proportion of their cases come from small apartment houses.
7. The maximum age of incidence for boys is 5 years, and for girls 6 years.

THE AETIOLOGY OF HEART DISEASE

BY

C. BRUCE PERRY, M.D., M.R.C.P.

ASSISTANT PHYSICIAN, BRISTOL GENERAL HOSPITAL

An analysis of the cases of organic heart disease seen by the late Dr. Carey Coombs in the wards of the Bristol General Hospital during the years 1918 to 1929 showed that acute rheumatism was the aetiological factor in over 55 per cent. Further, a three-year survey of the incidence of acute rheumatic heart disease in Bristol and the surrounding counties¹ provided strong evidence that the incidence of this disease was very much higher in the city than in the counties. For these reasons it appeared desirable to Dr. Coombs that an attempt should be made to assess the part played by rheumatism in the causation of heart disease in other parts of Great Britain. The trustees of the R. L. St. J. Harmsworth Fund interested themselves in this investigation, and by their help it has been possible to obtain the figures of the cardiac cases admitted to various hospitals of Great Britain for the year 1932. Information has been received from the following: Royal Infirmary, Aberdeen; Royal Victoria Hospital, Belfast; General Hospital, Birmingham; General Hospital, Bristol; Royal Infirmary, Bristol; Royal Infirmary, Cardiff; Western Infirmary, Glasgow; National Hospital for Diseases of the Heart, London; Royal Infirmary, Liverpool; Middlesex Hospital; Royal Victoria Infirmary, Newcastle; Norfolk and Norwich Hospital, Norwich; and Royal Hospital, Sheffield.

The classification adopted was as follows:

1. Congenital heart disease.
2. Rheumatic heart disease. In this group were included not only cases of heart disease with a history of rheumatism, chorea, tonsillitis, or scarlet fever, but also cases without any such history, yet conforming in type to the rheumatic pattern—namely, cases of (a) ventricular enlargement with mitral incompetence under the age of 40; (b) mitral stenosis with or without incompetence; (c) aortic incompetence with or without stenosis under the age of 30; and (d) acute fibrinous pericarditis. The inclusion of such cases in this group was, of course, conditional on the absence of any alternative aetiology.
3. Ulcerative endocarditis. In this group were placed all cases of infective lesions of the endocardium not already included under rheumatic or syphilitic; thus it included all cases of acute, subacute, and chronic bacterial endocarditis, endocarditis lenta, etc.
4. Cardiac syphilis. This group comprised cases of aortic incompetence, aneurysm, aortitis, and angina with a history of syphilis, positive Wassermann reaction, or the presence of signs of other syphilitic lesions such as tabes dorsalis.
5. Thyrotoxic heart disease. In this group were placed all cases with physical signs or symptoms of heart disease with evidence of past or present thyrotoxicosis.
6. Hyperpieis. Systolic blood pressures of 200 mm. Hg and over, even if only reported on one occasion, qualified for admission to this group, whether the patient also exhibited signs of arterial degeneration or not.
7. Senile cardiosclerosis. This term covered all cases of arteriosclerotic or "senile" heart disease, even though the "senility" was premature. The word "decreased" was considered, but rejected for various reasons. This group, of course, included the majority of cases of coronary thrombosis.
8. Functional. All cases of heart disease with no ascertainable organic basis were placed in this group, which included such diseases as "D.A.H.," paroxysmal tachycardia without organic lesion, sino-aortic block, etc.

9. Various. This group comprised cases with a definite organic change yet of a kind which did not fit in with the other groups. Such conditions as auricular fibrillation, congestive failure and heart-block with no ascertainable aetiology, heart failure secondary to chronic pulmonary disease, diphtheritic myocarditis, and terminal pericarditis were included.

The results of the investigation are given in the table. It must be borne in mind that these figures deal only with patients of the hospital class in Great Britain, and further that, with the exception of those from Liverpool, they refer only to patients admitted to hospital.

might be expected in the case of a not very common disease. The average incidence for the whole group is 2.3 per cent. of all heart cases. If it is assumed that in a general hospital one in five of the medical admissions is suffering from some form of heart disease (a fair average), this incidence approximates closely to Horder's estimate²—that bacterial endocarditis is found once in every 200 medical admissions. It is interesting to note that the hospital with the highest incidence of rheumatic heart disease (Cardiff Royal Infirmary) also showed the highest percentage of cases of ulcerative endocarditis; but the correlation between the two diseases holds no further than this.

	Aberdeen	Percentage	Belfast	Percentage	Birmingham	Percentage	Bristol General Hospital	Percentage	Bristol Royal Infirmary	Percentage	Cardiff	Percentage	Glasgow	Percentage	Heart Hospital	Percentage	Middlesex Hospital	Percentage	Newcastle	Percentage	Norwich	Percentage	Sheffield	Percentage	Liverpool	Percentage	Total for All Centres	Percentage

CONSIDERATION OF THE VARIOUS AETIOLOGICAL GROUPS

Congenital.—The figures in this group undoubtedly give no true indication as to the incidence of congenital cardiac defects. In the first place, many of the patients with severe malformations die in early infancy, and admission to hospital is rarely considered. In the second, many of the cases of less severe forms of congenital heart disease—for example, patent ductus arteriosus—present few or no symptoms, and in the absence of any engrafted infection or intercurrent disease would not need in-patient hospital treatment.

Rheumatic Heart Disease.—This was responsible for over 35 per cent. of the cardiac cases admitted to ten of the thirteen hospitals concerned. The maximum incidence recorded was 50 per cent. of the total heart cases at Cardiff Royal Infirmary, and the minimum—16.5 per cent.—at the Middlesex Hospital. This latter figure is rather surprising and difficult to explain, since the corresponding figure for the National Hospital for Diseases of the Heart, London, was 47.6 per cent.—one of the highest in the series. It may be related in some way to the very high incidence of thyrotoxic and hyperpietic heart disease at the Middlesex Hospital, due to the fact that special investigations were being made on these two types of heart disease. Another factor which may influence the figures is that very few heart cases are admitted to the children's wards, and Dr. Keele suggests that this may be in part due to the proximity of the Middlesex Hospital to the children's hospital in Great Ormond Street. The large part played by rheumatism in the causation of heart disease is shown forcibly by the fact that 38.4 per cent. of the cases in the whole series fell into this category. It is noteworthy also that the incidence of rheumatism at the different centres varied less than any other single aetiological group, with the exception of the Middlesex Hospital, which has already been discussed.

Ulcerative Endocarditis.—The figures for this disease vary quite considerably (from 0.6 to 5.6 per cent.), as

Cardiovascular Syphilis.—The variations in the incidence of this type of heart disease found at the various centres are most surprising and difficult to explain. It would appear likely that the incidence of syphilis must be roughly the same in all large cities, and yet we find the incidence of heart lesions varying from 1.75 per cent. of all heart cases in Liverpool to 12.6 per cent. in Aberdeen.

Thyrotoxic Heart Disease.—From the well-recognized influence of geographical conditions on diseases of the thyroid gland, the large variations in the incidence of heart disease from this cause might have been expected. However, there appears to be no very close geographical relation between the places with a high incidence or between those where the incidence is low. Part of the wide variation may be due to the fact that in some hospitals such cases are admitted to medical wards and in others to surgical ones.

Hyperpietic Heart Disease and Senile Cardiosclerosis.—There are wide variations in both of these groups. It is possible, however, that there may have been some confusion in the sorting of these two types of heart disease. If the two groups be added together there is much less variation in the incidence of the combined groups, although even then the figures by no means show an even incidence.

Functional Heart Disease.—The incidence of functional heart disease was high at Liverpool, where such cases formed rather a high percentage of the whole (17.2 per cent.). This is almost certainly due to the fact that the figures from all the other centres dealt only with hospital in-patients, whereas for Liverpool all patients attending Professor John Hay's clinic were included.

It might be argued that the marked variations noted in the different types of the disease merely served to show that such a study as this was worthless and the information gained unreliable. However, against this must be set the figures obtained from the two Bristol hospitals, where the cases are seen and diagnosed by two

quite distinct groups of physicians; these show a very marked parallelism.

The most obvious fact that emerges from this study is the strikingly constant and high incidence of rheumatic heart disease among hospital patients. It thus serves to show, if any further evidence is needed, the urgent necessity for further study into the aetiology of acute rheumatism and into methods for its prevention and relief. In view of the variations in the incidence of other types of heart disease, which are evident in this investigation, it would appear very desirable that such inquiries should be continued at different centres throughout Great Britain along similar lines for a longer period of time, so that it may be ascertained whether such variations are constant, and what local features are responsible for them.

B. PYOCYANEUS MENINGITIS WITH RECOVERY

BY

J. F. D. SHREWSBURY, M.D., D.P.H.

The following case of *B. pyocyaneus* infection appears to be of sufficient general interest to warrant its publication, partly because it points a moral, and partly because the precise pathogenic status of *B. pyocyaneus* for the human adult is still, somewhat doubtful. *B. pyocyaneus* has long been recognized as a secondary invading microbe in wounds and sinuses in man, but many authorities consider that it can only fill the role of a primary invader in infections of children and debilitated adults. Wilson¹ states, however, that the bacillus can produce in adults a generalized infection resembling typhoid fever, and that in the course of such an infection the bacillus may attack the meninges. He mentions that cases have been recorded of *B. pyocyaneus* meningitis resulting from the injection of contaminated cocaine solutions for anaesthetic purposes.

CASE REPORT

The patient, a married woman aged 34, was originally admitted to the surgical wards of the Queen's Hospital, Birmingham, under observation for presumptive attacks of gall-stone colic. This condition, however, bears no relation,

This investigation was made possible by a financial grant from the trustees of the R. L. St. J. Harmsworth Fund, and by the assistance of the following: Dr. R. J. Duthie, Aberdeen Royal Infirmary; Dr. T. H. Crozier, Royal Victoria Hospital, Belfast; Dr. B. Taylor, General Hospital, Birmingham; Dr. J. M. Thomas, Royal Infirmary, Cardiff; Dr. W. R. Snodgrass, Western Infirmary, Glasgow; Dr. Wyn Jones, Royal Infirmary, Liverpool; Dr. Doris Baker, National Hospital for Diseases of the Heart, London; Dr. C. A. Keele, Middlesex Hospital; Dr. A. G. Ogilvie, Royal Victoria Infirmary, Newcastle-on-Tyne; Dr. B. Morgan, Norfolk and Norwich Hospital, Norwich; and Dr. T. E. Gumpert, Royal Hospital, Sheffield.

and she vomited several times. Her temperature, which was normal on admission, rose precipitately to 100° F., and her pulse rate increased from 65 to 80.

There is a hiatus in the clinical record for the next fifteen days, but apparently she returned home, where she was confined to her bed and was attended by her own doctor. She was admitted to the medical wards of the Queen's Hospital on September 6th, 1933, and on the following day the examination of a sample of her cerebro-spinal fluid established the bacteriological diagnosis. The fluid was frankly purulent, and contained large numbers of a small, extracellular, actively motile Gram-negative bacillus, which proved to be *B. pyocyaneus* on cultural investigation. Between September 7th and October 10th seven samples of cerebro-spinal fluid were examined bacteriologically and biochemically, and the laboratory findings on these fluids are tabulated below.

On admission the patient presented the picture of a subacute meningitis. She was febrile (102° F.), with a slow pulse (60), and was vomiting at frequent intervals; she had a severe left-sided headache, with a tendency to localization in the occipital region, a coarse nystagmus to the right, and a considerable degree of neck rigidity. Kernig's sign, however, was negative, and her fundi were clear. The clinical condition fluctuated considerably during the succeeding four weeks. On some days she had little or no headache, and the meningeal symptoms were inconspicuous; at other times she was prostrated by an intolerable headache, and the meningeal symptoms were obvious. For example, when she was examined by Dr. Neale on September 16th he was unable to detect

other than an accidental one, to the meningeal infection; she had no symptoms or signs of meningitis at this time. Shortly after her admission to hospital, as part of the general surgical examination of her complaint an injection of 10 c.cm. of percaïne was given intrathecally, prior to a pelvic examination being carried out per vaginam. On the following day the patient complained of a very severe, generalized headache,

any appreciable abnormality in her condition, but two days later she had a severe recrudescence of headache and vomiting, and exhibited the signs of an acute meningitis. This recrudescence persisted, with slight fluctuations, until October 4th, from which date a rapid improvement set in, which progressed to a complete recovery without any further interruptions. The fluctuations in the clinical condition could

not be correlated with any similar fluctuations in the chemistry or the cytology of the cerebro-spinal fluid.

The patient was discharged cured on October 17th, 1933, after a stay of practically six weeks in hospital. Since her discharge she has had no recurrence of meningeal involvement, and at the present time she is able to undertake her normal household duties, and seems to be enjoying good health. She has not, apparently, experienced any recurrence of the original attacks of presumptive gall-bladder trouble, which first brought her to the Queen's Hospital.

The significant treatment consisted in the complete drainage of the cerebro-spinal fluid by repeated lumbar puncture, and the rectal injection of four ounces of a 25 per cent. solution of magnesium sulphate, morning and evening, for the first eight days after admission.

DISCUSSION

It would appear to be certain that the meningeal infection was connected with the intrathecal injection of the spinal anaesthetic. The patient exhibited no signs or symptoms of any intestinal infection when she was first examined, and the complete absence of fever and her general good condition negative any likelihood of a pre-existing generalized infection with *B. pyocyaneus*. At no time, also, had she any signs of a middle-ear or nasal sinus infection.

The exact source of the infection has not been established, but contamination of the percarine is a more likely event than contamination of the syringe or needle used in the intrathecal injection; especially in view of Wilson's observation, to which I have already referred. Unfortunately, the sample of percarine was not submitted for laboratory examination, and, in the absence of bacteriological proof of the contamination of the percarine with *B. pyocyaneus*, the exact source of the infection remains a matter for conjecture. This case, however, has several educational bearings—notably, the low virulence of a *B. pyocyaneus* infection of the meninges in a previously healthy adult, and the warning that it provides of the need for scrupulous asepsis and absolute sterility in the use of medicaments and apparatus for therapeutic purposes. Had the infecting agent been *Staphylococcus aureus* or *Streptococcus pyogenes* the final result would certainly not have been so favourable.

I wish to record my indebtedness to Dr. A. V. Neale, honorary assistant physician to the Queen's Hospital, under whose care the patient recovered in the medical wards, for his kind permission to publish the clinical notes of the case, and to Dr. H. I. Coombs, Ph.D., biochemist to the Queen's Hospital, for his kind permission to include the chemical findings on the cerebro-spinal fluid.

H. W. Siemens and J. H. Broekema (*Nederl. Tijdschr. v. Geneesk.*, January 13th) state that Holland is one of the European countries in which favus is most frequent. In Germany the disease is almost unknown, as is shown by the fact that in Munich only four cases were seen in the course of a year, in Kiel ten cases in eight years, and in Hamburg four cases in six years. In the Leyden district, on the other hand, 250 fresh cases were seen in less than four years. The prevalence of favus in Holland is attributed to the fact that a large proportion of the patients refuse treatment owing to their ignorance of the risks connected with the disease. Moreover, many Dutch physicians are said to be ignorant of the principles of the modern treatment of favus. The authors maintain that the disease can only be eradicated by enlightenment of the public, which could be effected by the formation of a special association. In the meanwhile it is desirable that favus should be added to the list of diseases infection with which debar children from attending school.

A FURTHER INVESTIGATION ON EXCRETORY TUBERCLE BACILLURIA

BY

J. MENTON, L.R.C.P. AND S.I.
BACTERIOLOGIST TO THE COUNTY OF STAFFORD

Despite the progress of modern research in the elucidation of many aspects of renal function, authorities still differ on the apparently simple question as to whether or not micro-organisms can pass through the healthy kidney. This problem has a clinical as well as a scientific interest. It has from time to time engaged the attention of various workers, so that the lack of unanimity is not due to want of interest.

Wysokowitsch¹ (1836), using various micro-organisms, found renal lesions essential for transmission. Others who have agreed with this view, with the organisms on which they have based their conclusions, are: Boccardi² (1888) (anthrax bacilli); Pernice and Scagliosi³ (1892) (*Staphylococcus aureus*); Sherrington⁴ (1893) (various organisms); Cotton⁵ (1895) (*Staphylococcus aureus*); and Lepper⁶ (1921) (coliform organisms). On the other hand, Sittmann⁷ (1894) concluded that the staphylococcus could pass through a healthy kidney. Great disagreement exists also on this question in regard to the tubercle bacillus. Kiellenthermer⁸ (1914) obtained negative biological results in guinea-pigs with the albumin-free urines of thirteen advanced tuberculous patients, whereas three of eleven specimens showing albumin, and taken from similar patients, were positive, although these three patients revealed no post-mortem evidence of genito-urinary tuberculosis. He therefore concluded that tubercle bacilli could not pass through a healthy kidney, but might do so through an impaired organ, although no actual renal tuberculosis was present. Medlar and Sasano⁹ (1924), after examining 30,000 serial sections of the kidneys of twelve tuberculous guinea-pigs and four tuberculous rabbits, formed the opinion that renal tuberculosis was present in every instance in which tubercle bacilli were found in the urine during life, and that there was no evidence to suggest the excretion of these organisms by a normal kidney. Bumpus and Thompson¹⁰ (1930) did not think it was possible for a normal kidney to filter tubercle bacilli from the blood stream into the urine. Rieder¹¹ (1931) found urogenital tuberculosis by operation, or post mortem, in all the eleven instances in which he had recovered tubercle bacilli from the urine. The present writer¹² (1932) found only one urine positive out of seventy-six single specimens from seventy-six patients with advanced pulmonary tuberculosis, and repeated examinations revealed persistent albuminuria in this instance. On the other hand, Foulerton and Hillier¹³ (1901) obtained six positive urines from six tuberculous patients without being able to find any post-mortem evidence of genito-urinary involvement. Churchman¹⁴ (1914), Brown¹⁵ (1915), Geisinger¹⁶ (1917), Caulk¹⁷ (1921), Hobbs¹⁸ (1923), Smith¹⁹ (1924), Ekehorn²⁰ (1923), and many other authorities, including Calmette, have expressed themselves in favour of the possible occurrence of excretory tubercle bacilluria. More recently, Ramel²¹ (1932) formed similar conclusions, believing that he had encountered six instances of transitory tubercle bacilluria; but this authority like some of the others expressing similar opinions, seems to have laid undue stress on normal renal function tests, and it is not clear if he cut serial sections to exclude active genito-urinary tuberculosis.

PRESENT INVESTIGATION

A healthy young adult rabbit excreting normal urine received 66.5 mg. of living human tubercle bacilli intravenously. Twenty-four-hour specimens of urine were tested chemically, microscopically, and biologically from the first to the sixth day inclusive. No abnormality and no evidence of the excretion of tubercle bacilli was found, despite the fact that the guinea-pigs inoculated with the urine were kept alive for several months. The rabbit, killed late on the sixth day, showed no macroscopic

changes, and serial sections of the kidneys failed to reveal tubercle bacilli, although significant collections of round cells were found scattered sparsely throughout these organs.

A second healthy rabbit was given 163 mg. of living human tubercle bacilli intramuscularly, and twenty-four-hour specimens of urine taken from the first to the third day inclusive did not show any chemical, microscopical, or biological abnormality. The animal was killed at the end of the third day. No tubercle bacilli were found in the kidneys; collections of round cells were present, but to a less extent than in the first rabbit.

Ten forty-eight-hour specimens of apparently normal urine from ten guinea-pigs with advanced tuberculosis were tested on ten healthy cavies with three positive results. None of the original animals showed frank tuberculosis of the kidneys microscopically, the brunt of the disease falling on spleen, liver, and lymphatic system. These kidneys, however, could not be considered normal, as they showed degeneration of the tubular epithelium, cellular foci in the interstitial tissue, and other changes which could be attributed directly or indirectly to the toxæmia and other constitutional effects resulting from the presence of tubercle bacilli in large numbers in the other organs. It is noteworthy that the three tuberculous cavies showing tubercle bacilli in the urine exhibited these renal changes more extensively than the remaining seven animals.

As previously seventy-six single samples of urine had been tested from individual patients, it was now thought advisable to do repeated tests on a smaller number of infected people to exclude the possibility of periodicity in excretion. Any patient showing albuminuria or other gross change indicative of renal abnormality was discarded. One hundred specimens of urine were tested biologically, this number being taken from twenty-two patients, ten suffering from advanced pulmonary tuberculosis with positive sputa, and twelve showing surgical tuberculosis in an active state—mainly of the bone and joint variety. Of the hundred samples, eighteen were twenty-four-hour specimens—twelve from the surgical and six from the pulmonary patients. One sample only, the fourth single specimen from a man suffering from advanced phthisis, gave a positive biological reaction, and ten further samples, including one twenty-four-hour specimen, failed to repeat this result, but all the later specimens of urine showed hyaline and granular casts, which had not revealed themselves in the first four specimens: if they had, this patient would not have been included in the investigation. At the time of writing the casts persist, but there is no albuminuria, and the renal function tests are normal.

DISCUSSION

The fact that the rabbit's urine did not show tubercle bacilli after the intravenous administration of such a large dose seemed to afford strong evidence against excretory bacilluria. One must remember, however, that the rabbit has a comparatively high resistance to human tubercle bacilli, and the possibility of rapid destruction of the majority of the micro-organisms by autolysis or other means at once arose; for the collection of round cells in the kidneys appeared to indicate that tubercle bacilli had reached these organs, and the failure to find them suggested that they had been destroyed. Comparatively few tubercle bacilli were found in the spleen and liver, and a large proportion of these organisms were held up in the lungs. Additional experiments confirmed this finding, which was first suggested by Mr. Sworn of Stafford as a possible explanation of the paucity of tubercle bacilli in the abdominal organs and in the arterial blood after intravenous inoculation. Further work is being done on this aspect. The fact remains, however, that although some of the organisms gained access to the general circula-

tion, probably even in greater numbers than in natural human infection, none were excreted in the urine.

The three cavies showing positive urines presented a different set of circumstances. Their urines were tested when they were in an advanced stage of disease caused by an organism to which they are highly susceptible—that is, the bovine tubercle bacillus. Their kidneys, although not obviously tuberculous, were subject to the strains of toxæmia and altered metabolism. Consequently, these results cannot be claimed as evidence of excretory bacilluria by the normal kidney, but can be put forward in support of the idea that tubercle bacilli may escape from a distant focus through this organ when it is impaired from causes other than renal tuberculosis.

The human positive urine can be similarly explained. The casts were few, but they were sufficiently persistent to point to abnormality.

CONCLUSIONS

The results of this investigation do not confirm the opinion that tubercle bacilli can pass through a normal kidney, but they support the contention that these micro-organisms may gain access to the urine in the absence of renal tuberculosis when the normal action of the kidney is impaired, either indirectly as the result of extensive tuberculosis elsewhere or in consequence of independent renal disease.

My thanks are due to Dr. J. Stevenson and Miss M. Mulvein for their kindness in securing the necessary specimens and for supplying the clinical details of the patients, and I acknowledge my indebtedness to Mr. B. R. Sworn of Stafford and Dr. T. V. Cooper for supplying me with some of the original references.

With the title of "What the City is Doing for the Public Health," Dr. G. H. Masson, medical officer of health for Port-of-Spain, Trinidad, has published a health week address, delivered at the Royal Victoria Institute, Port-of-Spain, on October 2nd, 1933. It reviews the various activities of the municipal council, including scavenging, removal of house refuse, water supply, sewerage and sewage disposal, slaughtering, markets, and food protection. The lack of attention paid to tuberculosis comes in for acid comment, most of the education work in respect of its prevention being undertaken by the Association for the Prevention and Treatment of Tuberculosis, with the tuberculosis dispensary as its centre of activity. There are tuberculosis wards at the Colonial Hospital, which play a useful part by housing open cases, but there is no sanatorium for the early and curable cases. The prevalence of this disease is attributed to the extent of bad housing and overcrowding. A tabulated comparative summary of vital statistics for the years 1922 and 1932 reveals the progress in the diminution of disease which has been achieved, and this simple and humorously written statement of the work of the public health department should enable future advances to be made, thanks to the creation of a more interested and more instructed public outlook.

Clinical Memoranda

RUPTURE OF THE DUODENUM

The following case would appear to be worthy of record in view of the rarity of recovery after this lesion. According to Schumacher¹ the mortality of this injury is 90 per cent., and Miller² has found only one successful case of operation for extensive rupture of the third part of the duodenum. Doubtless other cases of recovery have been reported since, but further references are not available at the present time.

A girl, aged 20, was involved in a motor accident on the night of July 9th, 1933. On admission to hospital she was found to be suffering from severe shock, and showed signs of a grave intra-abdominal injury; she had also sustained a severe wound of the left thigh, as well as multiple bruises and abrasions. It was decided to operate without delay, and, rigidity being most marked in the right upper quadrant of the abdomen, laparotomy was performed through a right upper paramedian incision with open ether anaesthesia. The peritoneal cavity was full of blood, and on further exploration a large rupture was found in the third part of the duodenum. The tear was approximately $1\frac{1}{2}$ inches long, diagonal in direction, and ran round the upper surface of the viscus. Duodenal contents were free in the peritoneal cavity, and there was also a small tear of the pancreas with much haemorrhage into all the surrounding tissues and into the lesser sac of the peritoneum. The tear in the duodenum was sutured transversely in two layers, the peritoneal cavity mopped as dry as possible, and drainage tubes inserted—one in the lesser sac through the operation wound, one from the area of rupture through the right flank, and one in the pelvis through a suprapubic incision. The wound was then closed, and the patient, who had received intravenous saline throughout the operation, was given a blood transfusion of 500 c.cm. The wound in the leg was cleaned and plugged with flavine, and paraffin and antitetanic and *B. welchii* serum were administered. The patient stood the shock of the operation well. Eserine, 1/30 grain, and 1/2 c.cm. pituitrin were given alternately every three hours until the bowels acted with an enema on the second day.

The following day the patient's condition was reasonably satisfactory, all tubes draining blood-stained serum freely. On July 12th the discharge from the lesser sac and the pelvis began to decrease rapidly, but that from the tube in the flank became more profuse and lighter in colour. During the next two or three days this discharge was so copious that special drainage measures were required, and a continuous suction apparatus was devised. The discharge showed the appearance and characteristics of pancreatic fluid, but little bile was present. On the 13th the patient became jaundiced, but this passed off in two or three days. On the 17th the discharge in the flank began to lessen, and by the 22nd had almost ceased, but signs of a duodenal fistula appeared at the drainage hole in the operation wound. This flow continued for some days, but eventually dried up. On the 20th a serum reaction with marked urticaria occurred.

The patient manifested an intermittent pyrexia for over a month, but a good deal of this could be accounted for by the condition of the wound in the thigh, which suppurated. This gradually cleared up, however, and the patient was discharged from hospital on August 22nd suffering from occasional slight attacks of indigestion, but otherwise apparently well.

I am indebted to the Director of Medical and Sanitary Services, Kenya, for permission to publish this case, and to Dr. J. A. Carman for valuable assistance in the contrivance of various types of drainage apparatus.

TRAUMATIC EXTRAPERITONEAL RUPTURE OF THE DUODENUM

Traumatic extraperitoneal rupture of the duodenum is a rare and dangerous abdominal catastrophe.¹ Thus out of 132 cases of traumatic intestinal rupture it was found that in twenty-three the duodenum was affected; in four only of these was the lesion extraperitoneal, and in seven the injury was entirely overlooked at operation. The prognosis is particularly grave²; only two out of eighty-five recorded cases recovered. Although the condition is well known and its mechanics thoroughly understood, yet its precise diagnosis is a matter of great difficulty. The following case, therefore, needs no further introduction.

L. T., a checker, while working behind his own motor lorry, was struck in the back by another motor lorry and pinned between the two for about five minutes. He was brought into the casualty department in a condition of profound shock, and complained of severe boring pain in the upper part of the right side of his abdomen passing through to the back. His pulse was 72, respiration 22, and temperature 97.6° F. His breathing was entirely thoracic, and he was rigid all over the right side of the abdomen and exquisitely tender and hyperaesthetic in his right hypochondrium and right loin. There was no diminution of liver dullness, and his left flank was resonant, but his right flank was dull—non-shifting. An examination of his urine did not reveal any abnormal constituents. The patient was treated for shock, placed under continuous observation, and a half-hourly pulse record taken. A steady rise in his pulse rate to 96, within two hours, indicated that surgical intervention was here imperative.

The abdomen was opened by a right paramedian incision. No escape of gas occurred, and no excess of fluid was seen in the peritoneal cavity. No lesion was detected in any of his abdominal or pelvic viscera, but a haematoma about two inches in diameter was seen behind the mesentery. The retroperitoneal region was therefore explored. The peritoneum was incised just to the right of the transverse colon, and this was then turned back. The retroperitoneal tissues were revealed bathed in blood and bile, and the second part of the duodenum was seen to be severed transversely for about seven-eighths of its diameter; the tear was completely extraperitoneal. The blood and bile were swabbed away, and the duodenum sutured end to end. The abdomen was then closed, Morrison's pouch being drained by a tube passed through the right loin. Recovery was complicated by collapse of the base of the right lung and right haemothorax—both the result of the accident. These conditions resolved under careful nursing. The odour of the slight discharge after a few days pointed strongly to a pancreatic leak; it was therefore examined for pancreatic ferment and bile.

Report.—Small amount of bile present.

Diastase: 50 units.

Trypsin: very small amount present.

Cultures: enterococci and *B. coli*.

The discharge gradually ceased, and henceforth progress was rapid.

The distribution of the pain was possibly due to the involvement of the pancreas (having regard to pancreatic lesions such as acute pancreatitis and adherent peptic ulcer). However, the intimate anatomical relationship of the two organs renders it highly improbable that the pancreas could escape involvement by trauma sufficiently violent to tear the duodenum. Hence the radiation of the pain as described above is of important diagnostic significance. The case also illustrates the value of a rising pulse rate as the criterion of surgical intervention in the treatment of the "acute abdomen," and the paramount importance of regarding all the findings in an exploratory laparotomy with due gravity and

¹ Berry and Giuseppe.

proportion ; in this case the important finding was that of a retroperitoneal haematoma in the duodenal region.

My thanks are due to my chief, Mr. C. Jennings Marshall, M.D., M.S., F.R.C.S., for his kindness in allowing me to write this note, and for his valued help and criticism in its preparation.

M. BLASKER, M.R.C.S., L.R.C.P.
House-Surgeon, Charing Cross Hospital.

AN UNUSUAL NEPHRECTOMY

The following case seems to be of much interest, and may be considered worthy of record.

The patient, an unmarried woman aged 45, first consulted me in the early part of November, 1933. She complained of pains in the lumbar region, which had been troubling her for two or three weeks and were increasing in intensity, but said that otherwise she felt perfectly well. On examination there was a large, well-defined cystic goitre, from which she stated she had suffered for eighteen years (ever since a pregnancy), and which had recently started to give rise to slight obstructive symptoms. There was also a marked spinal curvature, with a convexity on the left side, most prominent in the lower dorsal region. On abdominal palpation a large, freely movable, and somewhat tender swelling could be felt in the left iliac fossa. This had been increasing in size at a considerable speed, according to the patient, who had not mentioned its existence prior to the examination. A diagnosis of ovarian cyst was made. After some consideration as to whether it would be wiser to deal first with the abdominal condition or with the neck, it was decided to open the abdomen.

On November 20th, under avertin and ether anaesthesia, the abdomen was opened by a mid-line incision, and a large cystic swelling was revealed, which lay partly in the pelvis and partly in the lower left abdomen. On examination this proved to be not an ovarian cyst but a cystically degenerated kidney, which had been forced forward and downward by the spinal curvature. Owing to the curvature and deformity it was quite impossible to consider removing the kidney by the usual extraperitoneal method, for the lower part of the spinal column lay, owing to its rotation, directly behind the hilum and vessels: it was therefore decided to remove the kidney transabdominally. The same cause that prevented the reaching of the vessels from the retrolateral position made them more accessible from the abdomen, and they were accordingly ligated and the kidney removed through the abdominal incision. Two large calculi were completely obstructing the left ureter about three inches below the pelvis of the kidney, and these were removed. A long drainage tube was then inserted and brought out through the upper part of the wound, and the wound closed in the usual manner.

Except for a somewhat troublesome cough (due largely to the condition of the neck), which on one occasion caused a slight protrusion of omentum through the drain wound, the patient has made an uneventful recovery, and is now quite convalescent and summoning up sufficient courage to have her neck operated on for the cystic goitre.

On examination of the specimen the kidney showed a very small portion of undegenerated tissue at the lower pole, with enormous distension of the pelvis and practical disappearance of the calyces, the whole of the remaining part showing a complete cystic degeneration secondary to the obstructive stones in the ureter. Interesting features arising in the case were: (1) how this woman, who stands about 5 feet, managed to have a full-term child eighteen years ago when suffering from the spinal deformity and pelvic inclination, which she states were as bad at that time as they are now; and (2) how the kidney had reached this condition without causing more severe symptoms.

I am much indebted to Dr. F. B. Oliphant, C.M., and to Dr. G. W. Oliphant for their assistance.

Honorary Surgeon, Bridport Hospital.

Reviews

PLUMBISM AND NEPHRITIS

Chronic Nephritis and Lead Poisoning,¹ by Dr. L. J. JARVIS NYE, is a carefully prepared, well-thought-out, and suggestive book,¹ one which will repay the reader. Although the subjects dealt with mainly concern Australia, the treatise is yet interesting and helpful to all. The association of plumbism and nephritis on that continent has long been known, and has been attributed to the painting of the verandas of the wooden houses with white lead paint. In Queensland 1,250 persons died from nephritis between 1917 and 1926; 706 of these were females, and 544 were males, the highest incidence occurring in the years between 20 and 30. In New South Wales for the same period the mortality rates were 539 males and 556 females, whereas in South Australia the numbers were 30 and 120 respectively. As the number of deaths under 40 years of age was more than three times greater in one State than the others, the question has been raised as to the harmful influence of its more tropical climate, or of the operation of a toxin upon susceptible persons. It is not uncommon to find a whole family affected by nephritis and its members dying one by one, a circumstance which has suggested the presence of some factor operating in childhood, and exercising a sclerosing influence which increases with the passing of the years. The interstitial type of nephritis is the more common, and it seldom shows itself till adolescence. Although many of the children are not robust, are stunted, and have not the playfulness of those who are healthy, they seldom require medical attendance until adolescence is reached, when there are complaints of failing eyesight, nose bleeding, and severe headache. Albumin may then be found in the urine, the blood is deficient in haemoglobin, and the blood pressure is raised. Vomiting is a common symptom, and is attributed to a vicarious elimination of urea by the gastric mucous membrane, since it is followed by a marked reduction in the amount of urea in the blood. Vomiting, recurrent and uncontrolled, is usually a precursor of death. At necropsy the kidneys are found to be contracted, the capsule firmly adherent, and on microscopical examination there is a widely diffused interstitial fibrosis with degenerated glomeruli.

Discussing the aetiology of nephritis, attention is drawn to the influence of micro-organisms or their toxins, also to chemical poisons. When the kidney disease develops during convalescence from an acute infection, the probability is that it is due to a bacterio-toxin of streptococcal origin, frequently, in the case of children, the *Streptococcus scarlatinae*. It has for long been a matter of debate as to how far nephritis occurring after 30 years of age is a repercussion of kidney trouble which had been present in childhood and due to scarlet fever. Nye's experience does not lend weight to the supposition. There is no definite information that post-scarlatinal nephritis is a forerunner of adult nephritis.

In studying the literature of lead poisoning there is little reference to children suffering from plumbism in our own country, but, three decades ago, J. A. Turner drew attention to the prevalence of the malady in the children of North Queensland: 428 cases had been treated during 1917-26 in the Hospital for Sick Children in Brisbane. As regards plumbism Nye's opinion is that there is a personal as well as a familial susceptibility to the toxæmia, also that seasonal influences operate, as

¹ *Chronic Nephritis and Lead Poisoning*. By L. J. J. Nye, M.B., C.M. Sydney, Australia: Angus and Robertson, Ltd. 1933. (Pp. 145; illustrated. 12s. 6d.)

shown by the largest number of cases occurring in the warmest months of the year. The physical signs of plumbism in children differ from those in the adult, especially as regards paralysis. In adults it assumes the form of "drop-wrist," but in children it attacks mainly the lower extremities, both limbs being affected, and when the upper limbs are involved the paralysis is always more pronounced in the feet. The extensor muscles of the toes and the peroneal muscles are the more involved, giving rise to "toe-drop," but the tibialis anticus and gastrocnemius do not always escape. When in children the upper extremities are affected the muscles involved are, as in the adult, the extensors of the fingers and of the wrists, and nearly always bilaterally. Cerebral symptoms are rare, although the retina and ocular muscles may become affected. J. L. Gibson has advanced the opinion that the papilloedema of the retina and paralysis of the ocular muscles are caused by increased intracranial pressure, and this view is strengthened by the good results which have followed lumbar puncture. Whether the paralysis of the extremities in lead poisoning is due to anatomical changes in the spinal cord, to peripheral neuritis, or to changes in the muscles is still an unsolved problem.

As regards the frequency of plumbism in children in Australia, there is little doubt of it being the result of the type of paint used for covering and protecting the verandas of wooden houses. White lead is the pigment mostly used, and in warm weather the surface becomes chalky and dusty. Children frequently suck the raindrops on the railing, or the dust penetrates underneath the finger-nails. Many of the children are nail-biters or thumb-suckers, and as two or three children in one family may die from lead poisoning it is difficult not to incriminate the paint. Attempts are being made to find a substitute. A titanium compound is said to possess equal covering power to lead carbonate, and to be capable of similarly resisting the influences of the weather. Time and trial alone will show whether all the advantages claimed for it can be substantiated, and particularly its freedom from harmful influences.

THOMAS OLIVER.

SURGERY OF THE THORAX

The thoracic cavity is the last of the great body spaces to be invaded by the surgeon, and the increasing extent of the practice of thoracic surgery is evidence of its relative success. Textbooks on this subject in the English language are few, while the literature in the form of papers is rapidly assuming formidable proportions. It was necessary, therefore, that an attempt should be made to sift this material and to assess what will stand the test of time and what is ephemeral. This Mr. HOLMES SELLORS has set himself to undertake, as he states in the introduction to *Surgery of the Thorax*.² A wide experience is one of the essentials for this task, and it might be debatable whether the relatively small practical experience of the author (which he frankly acknowledges) is sufficient for a review of this type. On the whole, however, good judgement is shown in the general description of well-tried measures and the application of essential principles.

In certain respects the author deviates from the straight and narrow path of orthodox teaching, such as when he states that lipiodol will enter the communicating bronchus of an abscess the opening of which is of

sufficient size to allow pus to pass out on coughing. This is definitely against general observation; and in the acute and subacute abscesses the granulation tissue in the bronchus is the chief barrier to the entrance of the oil, but does not prevent pus slowly leaking out as the tension in the abscess increases. In the really chronic abscess and the long-standing bronchiectatic cavities the epithelium of the bronchial tubes spreads into the cavities and allows free communication, and into these lipiodol will pass relatively freely. We should have liked to see more emphasis laid upon the value of intercostal drainage in selected cases of streptococcal empyema, and especially in children, either as a temporary measure or in many cases as the sole surgical procedure. While the value of bronchoscopy in the cure of acute pulmonary abscess may be debatable, as a proportion of such abscesses will resolve spontaneously after rupture into a bronchus, we cannot agree with the author when he declares that "bronchoscopy is of comparatively little value in lung abscess when compared to bronchiectasis." In fact, it is doubtful if bronchoscopy ever cures a patient with established bronchiectasis—apart from the variety which is secondary to the presence of a foreign body. Although temporary alleviation is common, relapse is frequent soon after the end of the course of treatment.

In addition to diseases of the lung there are short chapters on the heart and pericardium, the diaphragm, and the oesophagus. The illustrations are clear and well reproduced, and the presentation and printing make for easy reading.

PHYSICAL METHODS OF TREATMENT

Dr. HEINRICH WOLF must have worked with rare perseverance and energy to have written his *Textbook of Physical Therapy*³ during the busy years of medical practice. Apart from chapters on special subjects contributed by colleagues, the book is based entirely on the author's personal experience in the various branches of physical medicine during the last thirty years. Its purpose is to consider the clinical aspects of diseases from the physical therapists' point of view, and to show how to select appropriate treatment for individual cases at different stages of disease. The physical therapist is enjoined to regard himself primarily as a physician, and to adapt his treatment to the physiological needs of his patient, avoiding the dangers of over-specialization. A book written from first-hand experience is almost always fresher and more spontaneous in style than one compiled from other sources, but Dr. Wolf's book is an exception to this; and the reader may find it sometimes laboured. But the field covered is wide, and the task of surveying it must have been arduous.

Part I is concerned with theory and principles, and describes the different kinds of physical treatment, their effects, and the technique of their application. In the chapter on electrotherapy the author's references to the uses of sinusoidal currents and Schnee baths suggest that in his hands these measures have not proved as useful as other workers have found them. Diathermy is treated briefly in this section, but its special uses are considered later in relation to genito-urinary diseases, and in the chapters on minor electrosurgery and diseases of the lower respiratory tract. In the chapter on massage four conditions are mentioned which the author finds amenable to treatment by osteopathic methods. Unfortunately for the reader the successful manipulations are not described,

² *Surgery of the Thorax*. By T. H. Sellors, M.Ch., F.R.C.S. Preface by R. A. Young, M.D., F.R.C.P. London: Constable and Co., Ltd. 1933. (Pp. xxiii + 519; 140 figures, including 11 plates in colour. 22s. 6d. net.)

³ *Textbook of Physical Therapy*. By H. F. Wolf, M.D. With a foreword by L. F. Barker, M.D., LL.D., and chapters by W. Bierman, M.D., A. A. Lilien, M.D., F. Jourd'art, M.D., and M. C. L. McGuinness, A.B., M.D. London: D. Appleton-Century Company. 1933. (Pp. xxviii + 409; illustrated. 21s. net.)

on the ground that it is impossible to give satisfactory descriptions of them.

The second part of the book, on the practice of physical therapeutics, commences by dealing at some length with fractures and describing them individually, whether or not there is need for special modifications in their physical treatment. Much of this could, with advantage, be omitted, so reducing the weight of the book, which is uncomfortably heavy to hold. While mentioning the format of the book, the good printing deserves comment, but nothing is gained by including in the text diagrams such as that of the microcephalic in Fig. 45. Part II continues with accounts of the application of physical measures to diseases of the different systems of the body, conditions not included among these being considered together in a later chapter. The account of the therapeutic use of hyperthermia is interesting, particularly in relation to the physiological changes taking place under the influence of heat. The final chapter, contributed by a gynaecologist, strikes a depressing note, and one feels that this writer has become a misogynist, or has never met a normal woman. On page 358 appears the statement: "A woman is as well as her ovaries permit her to be"; and on the next page: "A woman has been defined as a constipated being with a pain in her side." But the value of physical methods in preventive medicine is realized, though not expressed very clearly. For instance, on page 359, we read: "To properly insure the girl and woman against the wear and tear of life to which she is apparently destined, physical medicine should be applied to both parents before and after marriage."

As a textbook the value of the present volume would have been increased if Dr. Wolf had departed from his rule of not often quoting other authors, and had appended a list of references or bibliography. While not contributing much that is original to the study of physical therapeutics, it is an honest attempt to present a comprehensive account of the subject, in the hope that this will lead to a wider understanding of physical medicine and a more rational employment of physical methods of treatment.

EFFECTS OF UNEMPLOYMENT

Generalizations as to the physical, psychological, and social effects of widespread unemployment, and statistics and averages as to its extent and incidence, require to be corrected, or at least supplemented, by a study of individual cases and of small communities in which it is more than usually prevalent in order to obtain a true picture or conception of the situation. Unemployment is not merely an economic problem, but a human experience. As we pointed out in a leading article on "Children and Unemployment" in the *Journal* of November 25th last (p. 981) the fully authenticated statement that "the harmful effects of unemployment have not been widespread or severe" in relation to school children, is compatible with the very real existence of malnutrition and other conditions detrimental to health in disquieting numbers of actual cases dealt with by the Save the Children Fund. So, though a steady diminution of the numbers of unemployed persons is encouraging, and a certain comfort may be derived from a knowledge that their unemployment is continuous over any long period in only a minority of instances, and though there is no reason to question Sir George Newman's statement that "there is at present no available medical evidence of any general increase in physical impairment, in sickness, or in mortality as a result of economic depression or unemployment," we require, in order fully to appreciate what is actually happening, a knowledge of the history

and circumstances of individual cases, and of the personal results on body, mind, and character.

This constitutes the value of such a book as *Memoirs of the Unemployed*.⁴ It is compiled and edited by LANCE BEALES and R. S. LAMBERT, and purports to give "first-hand accounts, by the workless themselves, of the physical and mental effects of prolonged unemployment." There are two appendices, useful but of no very outstanding value, by Ruth Bowley, on "How the Workless Spend their Money," and by Dr. Morris Robb on "The Psychology of Unemployment from the Medical Point of View." The former gives details of the budgets of five families, and discloses, in the light of the recent British Medical Association *Report on Nutrition*, a not very judicious expenditure. The latter appendix adds a short account of seven individual cases to the twenty-five fuller autobiographical narratives which constitute the body of the book. These are of a varied character, both as to nature of employment, position in society, age, circumstances, and effects. They bear every mark of authenticity, and have been judiciously collected and arranged. They are simple and brief "memoirs," and, as might be expected, disclose in some instances shortcomings of character as well as the heroic endurance of sheer misfortune and suffering, and even in a few cases a surprising continuance of optimism and confidence. They may, with advantage, be read by all those whose daily life does not bring them into contact at first hand with examples of a similar nature.

RECIPES FOR CHILDREN

The medical officers of the Chelsea Babies' Club have written a useful little book, entitled *Recipes for Food and Conduct*,⁵ dedicated to Dr. Eric Pritchard, and containing a great deal of sound common sense on diet, clothing, sunshine, fresh air, and other matters of importance to doctors and mothers. It is refreshing to find in this work a healthy condemnation of patent foods, together with a warning about the use of synthetic vitamin preparations: this is certainly needed to counteract the influence of commercial publicity campaigns. The ingenious method of allowing the flat-dweller's child to get fresh air by means of a wire cage fitted outside the window should prove popular when more widely known, while the section on artificial feeding—better called unnatural feeding—contains the wise recommendation that all milk, of whatever grade, should be brought to the boil. The same section records the sensible dictum, "It is impossible to feed babies artificially by a fixed formula," a point which can scarcely be emphasized enough. Written in clear language, this little book can be warmly recommended to all interested in babies.

Miss MARGARET BUCHANAN's little book on *Nursery Nourishment*,⁶ with a foreword by Dr. Robert Hutchison, can also be recommended as a useful means of finding an answer to the ever-recurring nursery problem of "what to give them." The author seems particularly strong on puddings, and shows a real understanding of children in her recipes for boiled rice pudding, which, when cold, is to be beaten up with cream and served in custard glasses with chopped cherries on top.

⁴ *Memoirs of the Unemployed*. Introduced and edited by L. Beales and R. S. Lambert. London: Victor Gollancz Ltd. 1934. (Pp. 287. 8s.)

⁵ *Recipes for Food and Conduct*. By H. Waller, N. Langdon Lloyd, J. Gibbens, and C. Grosvenor Millis. London: The Babies' Club, Stanley Cottage, 35, Danvers Street, Chelsea. (Pp. 63. 2s. 6d.)

⁶ *Nursery Nourishment*. By M. N. Buchanan. London: Edward Arnold and Co. 1933. (Pp. 104. 3s. net.)

Notes on Books

To help the mother of a blind baby in her difficult task of bringing up the child satisfactorily the National Institute for the Blind has issued a special bulletin for her guidance.⁷ The pamphlet is intended for those cases where the baby, instead of being sent to a Sunshine Home, is reared at home. Though, apart from the sense of sight, blind babies and seeing babies are physically and mentally the same, unexpected differences occur in behaviour. It has been observed, for example, that many blind children do not crawl before they begin to walk. Things beyond their reach have at that stage no attraction for them. Picture books mean nothing to the blind child, but it is normal in its love for the jingle of nursery rhymes. The mother is recommended to pay particular attention to those with action, such as "Pat-a-cake" and "Ride a cock-horse." A blind child is inclined to develop mannerisms unknown among sighted children: holding the head down, pushing out a foot to feel the way when walking, and so on. Such mannerisms, which must be carefully checked, are generally due to lack of confidence.

Sir Leonard Rogers contributes an introduction to *Unclean, Unclean!* by PAOLO ZAPPA⁸ (translated from the Italian by Edward Storer), and thus corrects a sombre story of the horror of leprosy in Brazil by showing how this disease is losing its terrors thanks to modern methods of treatment. The long-drawn-out misery of segregation, as pictured in the book, is now fast fading as cure is shown to be increasingly possible. In the future this pathetic tale may have a useful part to play, recalling a time of hopelessness that is at last gradually coming to an end. The terrible mental and physical sufferings of the advanced leper are delineated, and may lead some to understand better the great work that has been undertaken by the British Empire Leprosy Relief Association. The exaggerated fear of infection still exists, and hinders progress. It is well, therefore, that such a book as this, with its portrayal of incidents and facts and the illuminating commentary thereon by a great leprosy expert, should be available for propaganda work, as well as for those who can appreciate a record of suffering and of noble self-sacrifice.

The book entitled *Genealogy of Love*,⁹ which has been translated from the German *Stammesgeschichte der Liebe*, contains a readable account of the development of sexual life from amoeba to man, with special reference to savage tribes. The work is illustrated by numerous excellent photographs of mating in the lower animals.

The *Official Year-Book of the Scientific and Learned Societies*¹⁰ has attained its fiftieth year of publication, and the event is marked by a foreword to the latest issue by Sir Richard Gregory, the editor of *Nature*. In this foreword Sir Richard calls to mind the many scientific subjects—among them biochemistry, mycology, x rays, tropical medicine, and hygiene—that have given rise to new societies during the last fifty years, all of which are included in the year-book. He expresses the hope, which we heartily endorse, that the publishers will continue to render to science the service they have done so efficiently by publishing this valuable work of reference.

The thirty-fifth annual issue, for 1934, of *Mathiesons' Handbook for Investors*¹¹ gives a concise record of Stock Exchange prices and dividends of selected securities for the past ten years.

⁷ *The Care of the Blind Baby*. N.I.B. Bulletins No. 6. With an introduction by Eric Pritchard, M.D. London: National Institute for the Blind, 224-8, Great Portland Street, W.1. 1934. (Pp. 20. 3d.)

⁸ *Unclean, Unclean!* By Paolo Zappa. London: Lovat Dickson, Ltd. 1933. (Pp. 191. 7s. 6d. net.)

⁹ *Genealogy of Love*. By C. Thesing, M.D. Translated by Eden and Cedar Paul. London: George Routledge and Sons. 1933. (Pp. x + 283. 15s. net.)

¹⁰ *The Official Year-Book of the Scientific and Learned Societies of Great Britain and Ireland*. 1932-3. Fiftieth annual issue. London: Ch. Griffin and Co., Ltd. (Pp. 171. 10s. net.)

¹¹ *Mathiesons' Handbook for Investors for 1934*. London: F. C. Mathieson and Sons. (Pp. 347. 5s. net.)

We have received the first part of a work on Chinese drugs,¹² by Dr. TSUTOMU ISHIDOYA of the Pharmacological Institute of the Imperial University of Keijo. The need for such a publication is shown by the fact stated in the preface by Professor Noriyuki Sugihara, that in spite of an extensive literature dealing with the numerous Chinese drugs in existence, no modern work on the subject has hitherto been available for European research workers. The present volume gives a concise account, in alphabetical order, of drugs from China, Manchuria, and Korea, arranged in five sections according as they are derived from herbs, leaves, flowers, seeds, or fruits. A photograph of each plant from which the drug is derived is inserted in the text.

¹² *Chinesische Drogen*. By Tsutomu Ishidoya. I Teil. 1933. Keijo: Pharmakologischen Institut der kaiserlichen Universität. (Pp. 138; 171 figures.)

Preparations and Appliances

A FIDDLE BRACE

Major MEURICE SINCLAIR, C.M.G., R.A.M.C. (ret.) (London, W.1), writes: On first inspection the fiddle brace illustrated herewith may appear to have been published before, and this modification is also made for me by Messrs. Down Bros., Ltd., 21, St. Thomas's Street, S.E.1. While similar to the one published, which has an ordinary chuck that will only fit a slight variance of sizes of drill points, the same principles of drilling are maintained. It has a good uniform rate of rotation, is powerful, drills a clear-cut cylindrical hole, and, moreover, is easy to control and does not obstruct the line of vision. It is supplied with six interchangeable chucks of graduated, various sizes, and a "bullet," which are not here illustrated.

This instrument is fitted with a chuck (as in Figure 80 published in my book *Fractures*), which will hold almost every form of drill point for hand drilling, and can now be made to

hold the "Kirschner's thread" as well, by screwing off the cap, and placing a chuck which suits the "thread." This thread has a pyramidal drilling point at one end, and is squared at the other in order to allow it to be made fast when in the chuck by gliding the point of the thread through the "telescopic housing" and securing the squared end, which is accomplished by screwing its butterfly nut down until it jams the thread. Now extend the telescope to such a length as to allow about half an inch of the thread to be seen beyond the housing. Having decided the direction, the trajectory of the thread should be visualized, and where its exit is going to be. Gently press the point through the skin on to the bone; take your bearings again, holding the ball of the brace in one hand, and by fiddling on the cogwheel with the other it is remarkable how easily the thread will pass through the bone, provided the thread revolves quickly under very light pressure and that there is no alteration in the direction of its path. While the thread progresses through the bone the telescope becomes shorter and shorter. Steel threads (2 mm. or 1 mm.) are preferable to the so-called stainless variety. There are, so far as I know, only two metals which remain stainless when they are moistened, and stainless steel is certainly not one of them. After the thread has been fitted into the instrument the whole can be sterilized.

ACRIFLAVINE CREAM

Burnol acriflavine cream (Messrs. Boots) contains about 1 per 1,000 of acriflavine dissolved in a base of which the chief ingredient is liquid paraffin. It is intended as an antiseptic but soothing application suitable as a domestic and first-aid remedy in a wide variety of minor conditions. The valuable antiseptic properties of acriflavine are well known, and hence the cream appears to be very suitable for the uses for which it is recommended. The cream is put up in tubes, which is a form particularly convenient for first-aid applications.

THE ROYAL COLLEGE OF SURGEONS

HUNTERIAN FESTIVAL

The Hunterian Festival at the Royal College of Surgeons of England was held on Tuesday, February 13th, in commemoration of the two hundred and sixth anniversary of the birth of John Hunter. In the afternoon Sir Cuthbert Wallace delivered the Hunterian Oration, which is published in full in the opening pages of this issue. In the evening a banquet was given in the College Library, the company being received by the President, Sir Holburt Waring, and the Vice-presidents, Professor G. E. Gask and Mr. Wilfred Trotter.

THE PRESIDENT'S REVIEW

After the loyal toasts had been honoured the President, in proposing the time-honoured toast, "To the Memory of John Hunter," briefly reviewed some of the important matters which had occurred in connexion with the College since the last Hunterian Festival two years ago. The outstanding event had been the building and completion of the Buckston Browne Surgical Research Farm at Downe (adjoining the former home of Charles Darwin) in Kent. This research institution had been founded and endowed by Sir Buckston Browne, who made a gift of £100,000 for the purpose. By the munificence of the Leverhulme Trustees, Sir Louis Baron, and the late Lord Melchett four research scholars have been appointed to work at Downe or at the research laboratories of the College in Lincoln's Inn Fields, in addition to the College research scholar. Much valuable original work had been done on surgical shock by Mr. O'Shaughnessy and Dr. Slome, who had reinvestigated the whole problem. Other important researches were being carried on in connexion with certain aspects of thoracic and abdominal surgery by Messrs. Knight and O'Shaughnessy, and on bone formation by Messrs. Willis and Thompson. In addition to these researches Sir Charles Ballance was continuing his very important work on the regeneration of nerves. Thus it would be seen that the Royal College of Surgeons was taking its proper place in surgical and biological research. Recently the Profit Trustees had allocated to the College £10,000, to be spent at its discretion on cancer research, and two cancer studentships of £500 per annum for five years, with an additional £200 per annum to each student to enable visits to be made to other seats of cancer research. The College had subsidized the radium beam therapy research at the Radium Institute, and a research on the treatment of cancer by massive x-ray radiation at the Mount Vernon Hospital. Speaking of recent changes in the senior personnel of the administrative and scientific staff of the museum, the President said that Sir Arthur Keith had resigned the post of Conservator after twenty-five years' service, and had become Master of the Research Farm at Downe. Mr. R. H. Burne, their invaluable physiological curator, had also resigned, and Mr. Cecil Beadles, the pathological curator, had died. To all three the College owed a great debt. Dr. John Beattie—associate professor of anatomy at McGill University, Montreal—had been appointed Conservator of the museum and director of scientific research; the other posts had not yet been filled.

In proposing the health of the guests Professor GASK welcomed first the eleven Hunterian Trustees who were present that evening, and then in a few complimentary words the various groups of other distinguished visitors—academic, legal, civic, medical, and administrative. He specially greeted Bishop Paget, whose father gave the Hunterian Oration fifty-seven years ago.

IDEALS FOR THE POST-GRADUATE SCHOOL

Sir AUSTEN CHAMBERLAIN, in responding to the toast, suggested that the reason for asking him to do so was the fact that he was chairman of the Governing Body of the British Post-Graduate Medical School "which we are now bringing to birth." In this, as in other matters, he

said, the University of the capital city of the Empire had a special part to play under the conditions of to-day. Experience had shown that co-education of the medical graduate and undergraduate in the same institution was not practicable, and he and his colleagues had come to the conclusion some time ago that they must create a new school which would build up its own traditions in line with those of the great and ancient medical schools of the metropolis, and in harmonious co-operation with the Royal Colleges. One of the obvious tasks ahead of the British Post-Graduate Hospital and Medical School at Hammersmith would be to give refresher courses to practitioners who had lost touch with the great centres where experience of new things was easily come by. That was an urgent need, but not the most important function of the school as he saw it. His ideal was that it should become the home and temple of British contributions to medical science in all its branches; the staff must include the very best men in each line of work, who would regard this appointment as the blue ribbon of the teaching profession in medicine. The school ought also to be a place of research. In these ways London would enhance its position as a great medical centre, keeping in the forefront of progress in medicine and surgery and drawing to it graduates from all parts of the world.

The health of the Hunterian Orator was proposed by Sir ARTHUR STANLEY, treasurer of St. Thomas's Hospital, who spoke in glowing terms of Sir Cuthbert Wallace's services in peace and in war, and of his great and beneficent influence upon the hospital and medical school to which he had devoted most of his life. The toast was received with enthusiasm, and Sir CUTHBERT WALLACE acknowledged it in a few sentences obviously spoken from the heart.

In the Hunterian Museum and other parts of the College a number of exhibits, specimens, and books, etc., had been laid out for the occasion. These included books relating to John Hunter and to recent discoveries in medicine and surgery, and specimens connected with pathology, anthropology and comparative anatomy, experimental surgery, and the history of medicine.

The company included, in addition to those whose names have been mentioned: Viscount Leverhulme, Lord Dawson of Penn, P.R.C.P., Lord Lamington, Lord Rutherford, Lord Moynehan, Lord Riddell, Lord Stanmore, Lord Horler, Sir John Bland-Sutton, Sir Farquhar Buzzard, Sir George Newman, Sir William Bragg, Sir D'Arcy Power, Professor Langdon Brown, the President of the Royal Society of Medicine (Mr. V. Warren Low), the President of the Radium Institute (Sir George Blacker), the President of the British College of Obstetricians and Gynaecologists (Dr. J. S. Fairbairn), the Principal of the University of London (Dr. Edwin Deller), the Treasurer of the Inner Temple (Mr. Howard Wright), the Treasurer of Gray's Inn (Mr. G. D. Keogh), the Masters of the Leathersellers' and Barbers' Companies, the Chairman of the Board of Control (Mr. L. G. Brock), the Chairman of the Representative Body of the British Medical Association (Dr. E. Kaye Le Fleming), and the Editor of the *British Medical Journal*.

The following members of the Council of the College also were present: Mr. E. W. Hey Groves, Mr. F. J. Steward, Mr. C. H. Fagge, Mr. W. Sampson Handley, Professor A. H. Burgess, Mr. Victor Bognar, Mr. Hugh Lett, Mr. Leoard Gamgee, Mr. R. G. Hogarth, Professor R. E. Kelly, Mr. A. James Walton, Mr. A. E. Webb-Johnson, Mr. G. Gordon-Taylor, Mr. R. C. Elmslie, and Mr. L. R. Braithwaite, with Mr. S. Forrest Cowell (secretary), Mr. W. R. LeFanu (librarian), and Dr. John Beattie (conservator of the museum).

A summary of current literature on water pollution research has been issued by the Department of Scientific and Industrial Research. The brochure contains abstracts Nos. 1 to 125, classified under the headings "Water Supplies," "Analysis and Examination of Water," "Sewage," "Trade Waste Waters," and "Pollution of Natural Waters." Included in the section on "Miscellaneous Subjects" at the end of the brochure is an abstract of a bibliography on the hygienic aspects of aluminium and aluminium utensils. The abstracts are published monthly, and may be obtained from branches of H.M. Stationery Office, price 2s. net.

British Medical Journal

SATURDAY, FEBRUARY 17th, 1934

THE HUNTERIAN ORATION

Once again, on Tuesday of this week, the Royal College of Surgeons of England has paid its pious tribute to the memory of John Hunter, who was born on February 14th, 1728. The endowment for this purpose was accepted by the College in 1813, and since 1853 the festival has been held every two years. In the Hunterian Oration for 1934, which appears in the opening pages of our present issue, Sir Cuthbert Wallace speaks of some of the chief characteristics of John Hunter's individuality, and with admirable effect he draws a picture of Hunter's career against the background of his times. He seeks to answer the questions, What are the outstanding differences between the learning and practice of medicine to-day and the conditions which obtained a hundred and fifty years ago? and, What would Hunter have thought of our present education? Hunter's own education was haphazard and fragmentary: its only regular part was the assistance he gave to his brother William in his anatomy school; the rest was picked up at intervals in various hospitals, and the whole extended over some twelve years. When we recognize that if there is one thing more characteristic than another in his career it is its originality, we are tempted to relate his self-education to this as cause and effect. Sir Cuthbert Wallace gives a vivid account of the state of medical training in those times; it usually took the form of apprenticeship in practice and in hospital, but so lightly did the staff of a metropolitan hospital regard their teaching duties that Hunter accused his colleagues of taking money from their pupils and apprentices and doing nothing to earn it. The truth is, of course, that Hunter's originality is not to be traced to any empty freedom, but to the fact that he learnt to teach himself. No doubt he would have done so under any conditions. To-day a man, whatever his originality, finds himself inevitably part of an elaborate professional organization; this is the chief difference between the field of medical practice now and then. The community has gained much by the change; opinion will vary as to whether something of opportunity has not been lost to the individual.

Sir Cuthbert Wallace refers at considerable length to Hunter's war service, and quotes with approval his view that military surgery should not be looked upon as in any way special except in its circumstances; he speaks with authority when he says that the Great War also introduced little improvement in the practice of the art, a remark with which, we think, the generality of surgeons will agree. Its outstanding effect has been the separation of the treatment of bone affections as a specialty, the justification for which remains to be

proved. An indirect effect, referred to in the Oration, has been the stimulation of the idea of organizing civil treatment after the manner in which the medical care of the Army was organized, and the progress in this direction in the last twenty years is obvious. The main theme of the Oration is, however, a comparison of medical education then and now, and Sir Cuthbert asks the question whether, in remedying the want of order in Hunter's day, we have not gone too far in standardization and in centralization of control? This is a question which needs debate, and it can hardly be gainsaid that the passion for curriculum-making has gone a long way towards regimenting every hour of the student's time. A curriculum which even approaches this is a danger to originality; whether it would have stifled Hunter is not a point which can be profitably discussed, but drill cannot be substituted for learning without tending to have this effect. Yet Hunter was one of the pioneers in the organization of teaching. How far would he have carried it? Certainly not as far as adopting a full time-table of drill teaching, by class and lecture and demonstration, as the main preparation for the one profession for which it is least suited. He lent his influence towards changing the defects in guidance which existed in his time, and we should receive no support from him if we wished for a return of the kind of freedom he experienced; but it may be claimed that he would have been on the side of those who would design medical education so that the student may learn for himself and be his own chief instructor. If this is the design which would give originality a chance and at the same time give it guidance it would appear to be the best for medicine; for in medicine the solving of practical problems is the life-work of the individual, and some spark of originality is needed for the successful solution of them all.

The Orator took the opportunity to discuss some other of our present habits in the light of John Hunter's career, and we commend to notice his remarks upon specialization and research. In regard to the first and its relation to educational practice, he certainly marks the right relation when he says that specialization must not lead to the crowding of undergraduate instruction, but should come only after graduation. The representatives of several specialisms are claiming to-day that, whatever happens to others, for the one they practise at any rate room must be found in the undergraduate course. Such claims have little regard to the actuality that in the five years between the ages of 18 and 23 what can be given to the student is a basis of knowledge and a right method; much of the application of these must be learnt afterwards, and to emphasize a specialty can only take away time which is needed for the foundations upon which it should be built. There are many wise words in this Oration upon problems that are occupying professional attention to-day, well worth reading and thinking over by all who desire perspective and balance in our medical training.

PROPHYLAXIS OF MEASLES, SCARLET FEVER, AND DIPHTHERIA

In a recent article J. G. Fitzgerald provides an interesting survey of the specific prevention of measles, scarlet fever, and diphtheria in Canada.¹ The Connaught Laboratories have been fortunate enough to maintain a supply of "convalescent" measles serum in doses of 5 c.cm. for practitioners in Toronto. In the control of scarlet fever, antitoxin and active immunization are employed. Dr. Frieda Fraser obtained toxin from 95 per cent. of thirty-four haemolytic strains isolated from scarlet fever and from 80 per cent. of 102 non-scarlet-fever strains; puerperal and miscellaneous strains produced as potent toxin as those from true scarlet fever. To produce antitoxin, Strain NY5, of "broad valency," is employed (this strain, we understand, is also mainly used in England). The prophylactic use of scarlet fever antitoxin has been highly promising. Between 1921 and 1924 there occurred among 26,000 children admitted to the Toronto Children's Hospital 120 cases of scarlet fever (0.5 per cent.); since then all Dick-positive children on admission have received a prophylactic dose (apparently 2 to 5 c.cm.), and twenty-three children developed scarlet fever (0.05 per cent.). Since eighteen of these, for various reasons, received no antitoxin, the morbidity among those receiving serum was 0.01 per cent. In the earlier period twenty-five cases of scarlet fever broke out among 406 "burns" admitted; in the later period, among 500 admissions no attacks occurred, except in nine patients who did not receive serum. The disease is also being combated by active immunization. Prior to active immunization 5 to 6 per cent. of the staff of the Children's Hospital in Toronto were attacked each year; since active immunization was adopted the percentage has been 0.4 to 0.7 per cent. This pleasing result recalls the equally successful work of Benson in Edinburgh and Harries in Birmingham. The dosage employed is not mentioned. Groups of Dick-positive children had been immunized with toxin partly detoxicated with formalin; the percentage becoming Dick-negative ranged from 63 to 83. For the prevention of diphtheria, sufficient toxoid for the immunization of a million and a quarter people has been issued. Canadian experience indicates that reactions following the use of formol-toxoid are very rarely met with in children under 6 years of age, and are infrequent until the eighth birthday is past. The "Moloney" (intra-dermal-toxoid) test, for detecting people likely to suffer from reactions during immunization, is employed and is satisfactory. "Moloney-positive" reactors are immunized with perhaps four doses of toxoid, ranging from 0.02 c.cm. to 0.1 c.cm. or more. Dr. N. E. McKinnon and Miss M. A. Ross² have analysed the "Moloney" reactions of about 30,000 children. Up to the age of 5 there were 1.5 per cent. of positive reactions; almost all these "reactors" were in their

fifth year. Fortunately, therefore, in the pre-school period, where immunization is most called for, we need not anticipate much reaction. Between the sixth and eighth year 5 per cent. of children were strongly "Moloney-positive." Dr. W. H. Park³ of New York is issuing toxoid, and finds that, two to three months after commencement of a series of three, or even two, injections of material containing about 10 flocculation units per cubic centimetre, above 90 per cent. of the children are Schick-negative. He advocates starting to immunize country children at 6 months of age and city children at 9 months; he is also hopeful that alum toxoid may be useful.

Dr. W. H. Shepard⁴ presents an interesting analysis of the efficiency of the ordinary methods of advocating immunization against diphtheria. When the "mass propaganda" by newspapers, posters, and radio was studied, it was found that of the 600,000 people in San Francisco only 120,000 were mothers or fathers. Therefore, approximately four-fifths of the advertising energy was wasted. A house-to-house canvass revealed that, of the immunizations, 60 per cent. were credited to the school clinic and 26 per cent. to the private physician. Among the reasons for failure to immunize, lethargy, ignorance, opposition, and economic reasons were given, in that order of frequency. The general argument indicates that personal following up of children from the notification of birth; and the activity of tactful health visitors, are most fruitful. It is said that the photographs of the children of leading citizens being immunized are good propaganda. The ingenious author points out that, when it was decided to control beri-beri in the Philippine Islands by inducing the people to eat unpolished rice, the most powerful appeal was a photograph of the Governor-General eating this nourishing cereal, with, it is supposed, apparent enjoyment. Thus opportunity opens doors to conscientious members of Parliament and lord mayors! It is a striking fact that the material for this investigation was supplied by the Metropolitan Life Assurance Company, which for some years past has had the rare vision to see that much expenditure on advertising the efficiency of immunization against diphtheria, and other health measures, is sound business.

Are we in England keeping abreast of our neighbours? Toxoid was employed by Nash in England in 1924, a few months later than Ramon's first work. Highly concentrated toxoid was made by M. L. Smith⁵ in 1932, and alum toxoid has been used by Saunders and others; O'Brien and Parish⁶ and Laurent⁷ have recently shown that toxoid with an unusually high antigenic unitage will smoothly and rapidly produce immunity in school children, in tuberculous patients, and in nurses. The ideal aimed at is that immunization may be so simple and free from risk of reaction that virtually all parents will wish their children immunized

² *Amer. Journ. Pub. Health*, 1933, xxiii, 600.

² *Ibid.*, 1933, xxiv, 496.

before attending school, and that the efficiency of immunization will be so definite that neither "pre-Schick" nor "post-Schick" tests will be called for. The attaining of this ideal is within sight; probably it would be more rapidly reached if keen immunologists and school medical officers of health had readier opportunities. But the English method is to proceed slowly.

COLOUR SATURATION

The Medical Research Council has issued the report of a piece of research work done by Messrs. Martin, Warburton, and Morgan on "The Determination of the Sensitiveness of the Eye to Differences in the Saturation of Colours." The well-known methods of additive colour mixture allow the production of mixtures of spectral colours with white. Observations of a series of such mixtures of white with a single spectral colour show that as the proportion of the spectral component increases there is an increase in that quality of sensation called "saturation." This saturation, like the colour itself, is a psychological entity which cannot be measured directly, but it can be correlated with the photometric proportions of spectral colour and white in the mixture. If the mixture be altered without a change in the hue wave-length or brightness, a finite change has to be made before any difference in saturation is observed between one field showing the modified stimulus and another in which the stimulus is unchanged. The amount of this change is known as the "purity limen," and the investigators have sought to find how this quantity varies. The determination is important in practical colorimetry, and may throw light on the nature of colour vision. It is known that spectral colours are not of apparently equal saturation, and it is possible that none is completely saturated. Several modes of experimentation were tried. Most satisfactory results were obtained by viewing the two contiguous halves of an illuminated field. The observer controls the purity of one half and the relative brightness of the two parts. Starting with matched fields the purity is varied until a colour difference is produced which cannot be made to disappear by an adjustment of relative brightness. The changes are perceived in steps. In all cases it is clear that the amplitudes of the steps increase as the change is made from white towards colour; there is a maximum at some intermediate point and a tendency for the steps to become smaller again as the spectral colour is approached. Further, it is considered that a "result of greatest significance emerges from the work in an indication of the existence of a *white* definable in terms of visual capacity rather than of aesthetic judgement. The *white* is the sensation corresponding to the stimulus from which the least discriminable steps in purity tend at first to increase in mixtures with all spectral colours starting from white towards the colour." Helmholtz attributed the great variation of relative luminosity between complementary amounts of the spectral complementaries to their differences of saturation, an idea developed by Sinden. The idea seems to be well founded.

"AIR-CONDITIONING" FOR THE PREMATURE CHILD

The number and variety of incubators which have been invented and discarded is a sufficient indication of the still unsuccessful search for a perfect environment for the premature baby. A recent monograph from Boston¹ suggests that Dr. Kenneth D. Blackfan and his associates have found a satisfactory method of controlling the temperature and humidity of the air in which a premature baby lives for the early weeks of life, and have thereby demonstrated a considerable lowering of mortality. The main point of the system was the establishment of what were called "air-conditioned nurseries." These consisted of three rooms, ventilated by means of a mechanical equipment situated in the basement of the hospital, which had sufficient capacity to produce about twenty-five changes of air per hour in each of the rooms. The inlet and outlet for the air in each nursery were planned to prevent any draughts, and a wide range of temperature and humidity of the air in the rooms was possible by elaborate systems of control. When a definite temperature or degree of humidity was desired these could be obtained irrespective of the weather conditions outside. Observations were made on three groups of patients: normal premature babies weighing from 1½ to 5 lb. and admitted to hospital from a few hours to several weeks after birth; congenitally diseased premature infants or those suffering from congenital anomalies and from other pathological conditions incident to premature birth; and premature infants with acute and chronic infections and infants dying within forty-eight hours after admission. As far as possible general hygiene, clothing, feeding, etc., were kept uniform, and these premature infants treated in the air-conditioned nurseries were compared with the figures for previous years in "unconditioned" nurseries, where, however, other factors were not altogether uniform. Despite this fundamental difficulty of assessing the exact value of the results obtained, these seemed to be striking enough to warrant certain conclusions. The humidity best suited for stabilizing the body temperature (and preventing various disorders) was about 65 per cent. at temperatures ranging from 75° to 100° F. according to the state of the infant and the body weight. Under these controlled conditions low body temperature and fluctuations in body temperature were still noted in the infants of the lowest weights, but heat regulation seemed to be more easily stabilized at a satisfactory level. The post-natal loss of weight was less and ceased in a shorter time in the air-conditioned nurseries, and the maximum gain in weight occurred in patients in those nurseries under the higher levels of humidity. Air conditions have appeared to be of great importance in the control of the digestive disorders likely to occur in premature infants. The incidence of disturbances referable to the digestive tract was about three times greater under low than under high humidity, while the duration of such disturbances was four times greater. The death rates varied according to weight, age, sex, and general constitutional state of the infants, but it was found that the gross mortality for infants of the lowest weight groups was about 29 per cent. lower in the air-conditioned

¹ Amer. Journ. Dis. Child., November, 1933, xlvii, Part II, 1175.

nurseries than in previous years in the unconditioned nurseries. Even more startling figures were obtained if the mortality rates were calculated by leaving out all deaths occurring within forty-eight hours of admission, deaths due to congenital malformations incompatible with life, and deaths due to acute and chronic infections present at the time of admission. The "net" rate under the old conditions was 28.9 per cent. During the last two years, with the air-conditioned nurseries with optimum ventilation and humidity always high, the "net" death rate was 0.7 per cent., only one infant dying apart from the exceptions mentioned. The improved methods in general medical and nursing care of premature infants which were adopted as a direct consequence of the installation of the rooms and the investigations carried out must come into consideration, but cannot wholly account for this striking reduction in mortality. Although the apparatus could only be available for institutions its use has demonstrated the great importance of control of environmental conditions and especially of humidity of the air for the premature infant.

CARBON DIOXIDE IN MEDICINE

The use of carbon dioxide as a rapid respiratory stimulant is now so general and its value so undisputed that a review¹ by Professor Dautrebande of its physiological and therapeutical properties is of especial interest. As the author points out, carbon dioxide can be regarded as a specific antidote for all forms of established and imminent respiratory syncope, whether accompanied by acapnia or not. Thus in carbon monoxide poisoning increased pulmonary ventilation resulting from an insufficient supply of oxygen to the respiratory centre leads to an abnormal loss of carbon dioxide. The administration of the latter gas, preferably in conjunction with oxygen, causes augmentation of pulmonary ventilation, and so encourages the elimination of carbon monoxide and the absorption of oxygen. In poisoning by substances such as methyl alcohol, morphine, and the barbiturates, which cause a primary depression of the respiratory centre, there is diminished pulmonary ventilation, leading to an increase in the alveolar carbon dioxide and a fall in the alveolar oxygen content. In these circumstances the administration of carbon dioxide and oxygen supports the rhythmic activity of the centre, maintains the arterial pressure at a reasonable level, promotes oxygenation of the tissues, and, in the case of a volatile poison, facilitates its excretion. In the treatment of poisoning of this nature it is essential that carbon dioxide should be given with the minimum of delay, and in the absence of an easily accessible supply of the gas in the form of a cylinder or otherwise the author advocates the use of exhaled air. This can be administered in conjunction with artificial respiration either by direct mouth-to-mouth breathing, or through wide-bored rubber tubing, or after collection in a rubber bag, and it constitutes a safe and efficient first-aid measure. Professor Dautrebande emphasizes the value of carbon dioxide to the anaesthetist, and he draws particular attention to the fact that the speed at which ether is absorbed by the pulmonary capillaries depends solely on the quantity carried to the lungs in a unit

of time. Accordingly, the effect of doubling the respiratory volume by the aid of carbon dioxide is the same as that produced by doubling the percentage of ether in the inspired air, and it follows that the judicious use of this gas permits a rapid induction with the minimum concentration of irritating ether vapour. He refers to the work of Davies and Gilchrist, who showed that the administration of carbon dioxide during ether anaesthesia was a potent factor in preventing both the incidence and the severity of post-operative vomiting; in addition, he recommends the use of this gas, not only during anaesthesia, but also for short periods during the four or five days following operations, as a prophylactic against the development of post-operative respiratory complications. The use of carbon dioxide as a prophylactic for angina pectoris is discussed, and the author recommends inhalation for fifteen to twenty minutes thrice daily of a CO₂-air mixture in which the proportion of the former gas is insufficient to increase visibly the respiratory rate.

DRAINAGE OF INTESTINE IN PARALYTIC ILEUS

The treatment of paralytic ileus remains one of the major problems of surgery. While the value of rest, hypertonic saline, and enemata in the early stages is universally recognized, there is no general agreement on what should be done when, after a fair trial, these measures have failed, and the patient presents the picture of increasing toxæmia, progressive distension and vomiting, and a rising pulse rate. Any further exposure and handling of the intestine cannot but lead to an increase of paralysis. For this reason, and also because operation is often deferred until the patient is hopelessly toxæmic, the operative results are bad. But the fact remains that many of these patients are saved by operation, and it is therefore necessary to inquire what is the procedure which will give a satisfactory outflow to the intestinal contents with a minimum of trauma to the gut. R. Bernard¹ gives a critical survey of the methods which have been used, with details of a small series of his own. Two—gastrostomy and spinal anaesthesia—are mentioned only to be condemned: the first because all its advantages without its disadvantages can be gained by gastric intubation; the second because, paradoxically, it is more dangerous in its success than in its failure, as it may lead to a greatly increased absorption of toxins from the lower bowel. Duodenal intubation is dismissed rather summarily. The merits and demerits of bowel puncture, enterotomy, short-circuiting, and enterostomy are fully discussed. Evacuation of the intestinal contents by puncture is difficult, tedious, and incomplete, requiring a prolonged operation and extensive handling. Aseptic in theory, it is rarely so in practice. Enterotomy, by which is meant an incision 2 or 3 cm. long in the most dependent loop of the eviscerated intestine, is a most rapid and effective method of emptying it, but is ruled out as unsuitable in paralytic ileus because its effective and aseptic performance necessitates evisceration. The operation of short-circuiting, made famous in English surgery, is long and severe. It leaves the toxic material in the intestine, and the colon can so little be depended on to deal with it that a caecostomy, in addition, is generally considered advisable. Moreover,

¹ *Bruxelles-Medical*, October 22nd, 1933, p. 1500.

¹ *Rev. de Chir.*, October, 1933, p. 606.

the exclusion of any considerable length of intestine leaves a state of affairs which will require still another operation after the patient has recovered. It is asked whether all this is justifiable when a high enterostomy is far quicker, safer, and at least as effective. A high enterostomy through a left para-umbilical incision is regarded as the method of choice. It is quick and easy to do, only requires local anaesthesia, and can be performed aseptically. The technique followed is similar to that of Witzel's gastrostomy. The tube can easily be withdrawn when its work is done, and spontaneous closure of the fistula is stated to be the rule. A high enterostomy is chosen because this is the last part of the intestine to lose its peristaltic power—the *ultima moriens*—and the first to regain it. The defect of the method is that it depends on the persistence or the return of peristalsis, and that as a means of passively emptying the intestine it is almost useless. This is the fundamental flaw in every operative method of approach to the problem. The condition, after all, is paralysis, and every laparotomy and manipulation of the gut can only aggravate it. Their good effects, if any, are incidental.

HEALTH OF THE FRENCH AIRMAN

Professor René Cruchet, whose name has for long been associated with the medical aspects of aviation, has recently traced¹ the development of this branch of medicine in France since the end of the war. During it, airmen were medically examined on the lines adopted for the other Services, and it was not till 1919 that a special examination was introduced. In October, 1933, Annex E to the international convention governing aviation provided for the medical control of the pilots of public aircraft both before and during their service. In 1920 Professor Cruchet and Dr. Moulinier published their work on airmen's ailments—a book which was promptly translated into English. The years between 1920 and 1926 saw certain modifications in the tests and regulations affecting airmen's health, but since the latter date no great changes have been necessary. At the present time five different forms, representing five different medical examinations, have to be filled in: Medical, radiological, neurological, oto-rhino-laryngological, and ophthalmological. At Bordeaux, out of a total of 1,494 candidates for entry to the air service between May 18th, 1921, and the present time, as many as 592 have been disqualified either temporarily or permanently. This implies a high standard, and the authorities have been criticized for rejecting as great a proportion of candidates as 39.65 per cent. But this high standard has had a salutary effect in raising the general level of the applicants, who have learnt that only the very fit can be accepted. A classification of the disqualified applicants shows that as high a proportion as 41 per cent. failed on account of their eyes, and 23 per cent. on account of their respiratory systems. A faulty general constitution was responsible for 13 per cent. of the disqualifications, and a faulty nervous system for only 1 per cent. The medical examinations for civilian pilots yielded a much lower disqualification rate (7.46 per cent.), for the simple reason that most of the candidates had already served in the air force.

¹ Journ. de Méd. de Bordeaux, November 20th, 1933

Professor Cruchet has learnt to recognize a characteristic airman's heart, one which is demonstrable even in men of apparently good physique. As for the air future of this picked body of men, it is short enough in all conscience. A man may continue in full activity till he is 40, but that is the limit, beyond which he will find his circulatory system failing him. He may take short flights and "*promenades de tourisme aérien*," but for long flights he is too old after this age.

JUBILEE OF THE "ANNALS OF SURGERY"

We congratulate the *Annals of Surgery* on attaining its fiftieth year.¹ Messrs. Lippincott, the publishers, celebrate the event with a special cover resplendent with gold, as is fitting in a country possessing most of the world's stock of the metal. They have, however, with undue modesty, hidden a short account of the *Annals* on the back of this cover, where it is likely to be overlooked and will be lost except to those owners who direct their binders to "put the covers at the end" of the volume. As befits the occasion, the number is exceptionally good both as regards the paper, the printing, and the letterpress. It is enriched by a life-like portrait of Dr. L. S. Pilcher, with his eulogy written by Dr. J. P. Warbasse. It appears from this eulogy that Dr. Pilcher entered the University of Michigan when he was aged 13, took his bachelor's degree at 17, served as a hospital steward—we should call him a dresser—during the American Civil War in 1863, was appointed an assistant surgeon in the United States Navy in 1867, and became the first editor of the *Annals of Surgery* when it began its career in 1884. His name still appears as editor on the title-page of this jubilee number. We wish him continued health and strength to perform his editorial duties. The *Annals of Surgery* has always maintained an intimate connexion with British surgery. Mr. C. B. Keetley, Sir Frederick Treves, Sir Watson Cheyne, and Sir William Macewen performed in succession the duties on its staff which are now so worthily carried out by Mr. Sampson Handley.

The Milroy Lectures, on international co-operation in public health, its achievements and prospects, will be delivered by Sir George Buchanan before the Royal College of Physicians of London on February 27th and March 1st; the Goulstonian Lectures, on hormones and their chemical relations, by Professor E. C. Dodds on March 6th, 8th, and 13th; the Lumleian Lectures, on glandular fever and infective mononucleosis, by Dr. H. L. Tidy on March 15th and 20th; the Oliver-Sharpey Lectures, on viruses in relation to the aetiology of tumours, by Dr. C. H. Andrewes, on May 1st and 3rd; and the Croonian Lectures, on arterial hypertension, by Professor O. L. V. S. de Wesselow, on June 5th, 7th, and 12th. The lectures begin at 5 p.m.

Lieut.-General Sir Harold B. Fawcus, K.C.B., whose forthcoming retirement from the post of Director-General of the Army Medical Services we announce on another page, has been appointed Director-General of the British Red Cross Society, and will take up his duties at 14, Grosvenor Crescent, S.W., on March 1st.

¹ *Annals of Surgery*, xcix, No. 1, January, 1934.

RESEARCH SCHOLARSHIPS IN MEDICINE

LADY TATA MEMORIAL TRUST

This trust was founded and endowed in April, 1932, by the late Sir Dorabji Tata of Bombay as a memorial to his wife, the late Lady Tata, in order to promote the advancement of medicine by research into the diseases of the blood, with special reference to leukaemias. Provision is made under this trust for research scholarships, fellowships, prizes, and grants in aid of research work. With the exception of one-fifth of the net income, earmarked for the encouragement of research by Indians in India or abroad, the rest will be devoted as stated above, and the awards will be open to candidates of any nationality, including India. The trustees are advised by an advisory committee having its headquarters in London, including Continental representatives, and by an Indian committee in India.

In June, 1933, the first four Lady Tata Research Scholarships were awarded.¹ Announcement is now made that four further scholarships, of the value of £400 a year each, will be open for award in June, 1934, to men or women of any nationality for research work in the subject of blood diseases, with special reference to leukaemias. Each will be tenable for a year from October 1st, 1934, and renewable up to a normal maximum tenure of three years. The scholarships will ordinarily be awarded on a whole-time basis, but a candidate holding a part-time teaching post may be allowed to retain this if, in the opinion of the trustees as advised by the committee, his duties will not prevent him from giving his chief interests and energies to his proposed research work.

Candidates for these scholarships must send their applications in time to be received in London on April 15th next, addressed to the secretary, Dr. H. S. Patel, Lady Tata Memorial Trust, Capel House, New Broad Street, London, E.C.2, or Professor A. Vacha, Calvinstrasse, 27, Berlin, N.W.40, or the Lady Tata Memorial Trustees, Bombay House, 24, Bruce Street, Fort, Bombay, from whom forms of application may be obtained. Applications which are delayed by special circumstances will be accepted up to April 30th, but in no case later.

A candidate at a distance who may be unable to obtain a form of application in time will be considered if his (or her) name, age, sex, nationality, and qualifications are given, together with the proposed line of research and the methods to be used, the institute or laboratory in which this is to be done, and the director who will supervise it. Testimony in confidential letters addressed to the secretary should be sent at the same time by not more than three persons able to speak from personal knowledge of the candidate's character, ability, and experience.

PRECAUTIONS AGAINST ELECTRIC SHOCK

The attention of the British X-Ray and Radium Protection Committee has been drawn to a series of accidents involving electrical shock. It is recognized that, with the more powerful plants in use to-day the possibilities are that such shocks might prove fatal. These dangers have already been dealt with in the committee's recommendations, and are referred to in the revised recommendations, which read as follows:

Electrical Precautions in X-Ray Rooms

1. The floor-covering of the x-ray room should be of insulated material such as wood, rubber, or linoleum.
2. Where permanent overhead conductors are employed they should be not less than 9 feet (3 metres) from the floor. They should consist of stout metal tubing or other coronaless type of conductor. The associated connecting leads should be of coronaless wire kept taut by suitable rheophores.
3. Wherever possible earthed guards or earthed sheaths should be provided to shield the more adjacent parts of the high-tension system. Unshielded leads to the x-ray tube should be in positions as remote as possible from the operator and the

patient. The use of "shock-proof" x-ray equipment in which the high-tension circuit is completely enclosed in earthed conductors is specially recommended. Unless there are reasons to the contrary, metal parts of the apparatus and room should be efficiently earthed.

4. Main and supply switches should be very accessible and distinctly indicated. They should not be in the proximity of the high-tension system, nor should it be possible for them to close accidentally. The use of quick-acting double-pole circuit breakers is recommended. Overpowered fuses should not be used. If more than one apparatus is operated from a common generator, suitable high-tension multi-way switches should be provided. In the case of some of the constant-potential generators, a residual charge is held by the condensers after shutting down. A suitable discharging device should therefore be fitted.

5. Some suitable form of kilovoltmeter should be provided to afford a measure of the voltage operating the x-ray tube. Wherever possible a safety spark-gap should be provided.

6. Special electrical precautions should be taken in rooms where low-flash-point anaesthetics are used in conjunction with x rays.

The committee now desires to emphasize the great importance of these precautionary measures to all persons responsible for or working in x-ray departments. Every step possible should be taken to prevent accidental contact with any part of the high-tension system, including the tube, the leads, and the associated measuring instruments.

While the use of shock-proof x-ray equipment in which the high-tension circuit is completely enclosed in earthed conductors is specially recommended, much can be done with existing apparatus in the way of providing relatively simple devices such as earth guards to shield the more adjacent parts of the high-tension system. Mobile units in particular should be carefully examined before their use in the case of every patient. Further, schemes of suitably illuminated warning notices which function when the equipment is "alive" are found to serve a very useful purpose. Printed first-aid instructions¹ for dealing with electrical shock should be available and the staff trained in their use.

England and Wales

British Industries House, London

British Industries House, the building put up by Gamages in Oxford Street, has been acquired by a combination of some of the leading assurance companies, who are equipping it as a place where the manufacturer of British goods can bring his wares to the notice of buyers. They have secured the interest of the Department of Overseas Trade, the Scottish National Development Council, and many important Chambers of Commerce, and other similar bodies all over the world. Lord Derby has given it his warm support, as a project for the promotion of British trade. Those responsible for the scheme resolved to have a medical department in which British manufacturers could show their most representative products, so that buyers could see them side by side instead of having to tour the country to make their purchases. The directors, believing that such a section should be run on lines which would be approved by the medical profession, asked Dr. Alfred Cox to advise them, and he suggested the appointment of a small medical advisory council, which could guide the business people as to the lines of general policy. Dr. Cox accepted the chairmanship of this committee, and Sir Crisp English, Dr. E. P. Poulton, and Mr. A. R. Melhuish, past-president of the Pharmaceutical Society of Great Britain, have accepted membership.

¹ British Medical Journal, June 24th, 1933, p. 1137.

¹ Printed cards of this kind are issued by the Electrical Review office, 4, Ludgate Hill, E.C.

Hunterian Society

The annual dinner of the Hunterian Society of London was held at the May Fair Hotel on February 8th, with the president, Mr. W. E. Tanner, in the chair. After the loyal toasts had been honoured, Judge Cecil Whiteley proposed the health of the Hunterian Society. He excused himself from making any biographical reference to John Hunter as he felt sure members of the society must already have heard a good deal about him. Instead he discoursed humorously on a subject which had recently come before the society—the value of alcohol to the citizen. Alcohol, he said, had been of great financial value to his own and to the medical profession. The president, in a brief reply, reminded his audience that Hunter had died in 1793, in St. George's Hospital, only a short distance from where they were dining. "The Corporation of the City of London" was proposed by Professor John Eyre. The Hunterian Society, he said, had on many occasions accepted the hospitality of the City of London, and they were very glad to have with them on this occasion Sir Charles Batho, who had always had the interests of the community and the medical profession at heart. Replying briefly, Sir Charles remarked that the Hunterian Society had done, was doing, and always would do, great work in the interests of the profession. He himself had always tried to do his best for the hospitals of this country. The toast "The Guests and Kindred Societies" was proposed by Dr. C. F. Hadfield. Having welcomed the chief guests individually he thanked Sir Charles Batho and other members of the Corporation of the City of London and the Cutlers' Company for all that they had done for St. Bartholomew's Hospital. Lord Horder thanked the members of the Hunterian Society for their hospitality and entertainment, and Mr. P. J. Hannon, M.P., also replied on behalf of the guests.

Medical Treatment after School Age

The Education and Central Public Health Committees of the London County Council brought up a joint report to the Council on February 6th on the question of providing preventive and curative treatment for children between the ages of 14 and 16 years. There is no power for a local authority to spend money out of the education rate on the medical inspection or treatment of young persons not attending educational institutions. The State does not provide for persons between 14 and 16 who have left school. By the provisions of the Education Act, 1921, however, a local authority has certain duties in this respect regarding young persons attending secondary, continuation, and other provided schools. Persons above the age of 14 attending secondary and trade schools have the benefit of the L.C.C.'s school medical service, but there are eleven voluntary day continuation schools maintained by the Council in which no medical service has been provided, and there is no medical service at the evening institutes, where it is estimated that some 30,000 persons between these ages attend. As an experiment for one year a scheme is now to be applied to the day continuation schools and to three junior evening institutes (in Bethnal Green, Battersea, and Shoreditch). Medical inspection will take place between three and six months after admission. It will be explained to the students that inspection is voluntary, and parents will be informed and invited to attend. At the day continuation schools about twenty-five students will be submitted for inspection at each visit (of about two and a half hours' duration) of a medical officer, and twenty students at the evening institutes, in a session of about two hours. Any student noted as requiring medical treatment will be advised accordingly, and where such treatment cannot be arranged on the student's own initiative, application will be made by the principal of the school or institute

for voucher cards for treatment under the Council's general school treatment scheme, where possible, or, if necessary, in the evening. Reinspections of students with defects are to be made in alternate terms. At the evening institutes where a class is held in health subjects the lecturing medical officer will be, if possible, the inspection medical officer. If necessary, convenient treatment sessions will be provided at the treatment centres in the evenings for students who cannot attend the day centres. It is estimated that 3,000 students at the continuation schools and 900 at the three selected institutes will undergo the voluntary medical examination. The total expenditure is estimated at less than £500.

Presentation to Dr. M. W. Renton

A farewell presentation was made on February 1st to Dr. M. W. Renton, who recently retired from the post of medical superintendent of the Dartford Institution. There was a large gathering of medical colleagues, officials, staff, and friends in the dining hall of the hospital. Mr. E. J. Hobbs, clerk of the Dartford Guardians Committee, and the senior official present, said that Dr. Renton had been medical superintendent for nearly a quarter of a century. When the guardians determined to re-establish the hospital on more up-to-date lines after the war Dr. Renton, by his great skill and organizing ability, was largely responsible for the clinics, the nurses' training department, the admission of private patients, the appointment of a staff of eminent specialists, and for bringing the work of the hospital to its present high state of efficiency. While losing him as medical superintendent they welcomed his appointment as honorary consulting surgeon. Dr. T. S. Cochrane, on behalf of the medical and nursing staff, paid a tribute to Dr. Renton's inspiring energy and ability, and spoke of the affection and respect they all had for him. After other speeches Mr. Hobbs presented Dr. Renton with an inscribed silver salver, a gold wrist-watch, and a handsomely bound illuminated address, containing a list of nearly 150 subscribers.

Society of Radiographers

The thirteenth annual dinner of the Society of Radiographers was held at the Restaurant Frascati, London, on February 10th, under the chairmanship of its president, Dr. L. A. Rowden of Leeds. Dr. Duncan White, who deputized for Dr. Stanley Melville, president of the British Institute of Radiology, proposed the health of the society. In complimenting the honorary secretary, Mr. Frederick Melville, and the executive council upon their wise guidance, he mentioned that the council had recently circulated an open letter pointing out that the profession of radiography at the present time had an ample number of recruits, if not too many. Dr. Rowden, in responding, took up the same point. While he did not think that the openings for radiographers were by any means exhausted, the appointments at the larger hospitals were now fairly well filled, and there remained the work in the smaller hospitals and in private practice, where, quite probably, it would be found that a second qualification, in massage, physical treatment, or nursing (two-thirds of the members of the society were women), would be very desirable from the point of view of the applicant. The register of technicians in subjects ancillary to medicine was getting into shape; it was due to the initiative of the British Medical Association, and its results would be to attach the Society of Radiographers more closely to the medical profession. The membership of the society had increased greatly during the last five or six years, and now numbered 760, scattered all over England and Wales, with some in Scotland and Ireland; and branches in Australia, New Zealand, and South Africa. Dr. Douglas Malpas welcomed the guests and visitors, and three responses were made to the toast of their health. Mr. R. C. Elmslie, chairman

of council of the Chartered Society of Massage and Medical Gymnastics, associated himself with what had been said about the dual qualification. In small country hospitals a dual qualification would be of real value; he suggested that the second qualification should be massage rather than nursing, because it was easier to obtain, and the radiographer who was also qualified to give massage could render very effective service in small hospitals. Mr. Elmslie added that as an orthopaedic surgeon he spoke for a branch of medicine which required greater assistance from the radiographer than any other. He welcomed the idea of the register of medical auxiliaries. To employ an unqualified radiographer was extremely unfair to the individual himself, because while he was in such employment he was not encouraged to obtain the necessary qualification, and without it he found himself at a grave disadvantage when his employment terminated. A proper qualification was essential for the radiographer, either in hospital or private practice. Further responses were made by Dr. G. W. C. Kaye of the National Physical Laboratory, and by Dr. E. Thorpe, president of the Birmingham Radiographic Society, while other speakers were Mr. C. W. Furby, the past-president, and Miss K. C. Clark, the first lady to occupy the position of vice-president. The Archibald Reid medal for a thesis on radiography was presented, for the second time, to Mr. M. Leman of Belfast.

Scotland

Carnegie Universities Trust

At the annual meeting of the Carnegie Trust for the Universities of Scotland it was mentioned that during the last four completed academic years the total number of students attending the Scottish Universities had been approximately 12,000 each year, with only a variation of about 1 per cent., and it was doubtful if any further increase would be wholesome. Principal Sir Thomas Holland, however, stated that in Edinburgh there were some 500 or 600 students from over-seas, who went back to their own countries when they had finished their studies, thus diminishing the risk of unemployment. In medicine there were 200 fresh students every year, but most of these went away, and it was believed that they all obtained employment. The Trust still pursued the principle of paying the fees of necessitous Scottish students, and during the past year the amount repaid by former beneficiaries had been £1,702. With regard to research the chairman, Lord Sands, said that chemistry, particularly organic chemistry, presented the most openings to-day. The Trust received more applications from men exceptionally well qualified in chemistry than from any others. During the past five years, out of fifty-seven chemistry scholars there had been seventeen physical chemists. In organic chemistry the fifteen Fellows to whom awards had been made published over thirty papers, which were said to constitute a very substantial contribution to current advances in this subject. Attention was drawn to the important researches at St. Andrews on the chemistry of sugars and terpenes. At the laboratory of the Royal College of Physicians, Edinburgh, which was supported by the Trust, eighteen workers had been engaged in research during 1932-3, and a fresh and promising line of research on industrial diseases had been started in co-operation with the Factory Department of the Home Office. During the thirty years of the Trust's operations the total number of awards for scientific research had been 2,982, and the total publications received had numbered 227 volumes and 2,002 other original contributions. The expenditure on research for the first quinquennium, 1908-13, had been £27,754, rising to £69,268 in 1928-33, with a gross total of £250,772 for the period of thirty years.

Crichton Royal Institution

The annual report of Dr. C. C. Easterbrook, physician-superintendent of the Crichton Royal Institution, Dumfries, shows that the number of patients under treatment during 1933 was 1,283. The number on the register at the close of the year was 989, including 458 males and 531 females. There were 642 private patients—of whom 278 were voluntary and 347 rate-aided patients. The certified patients had numbered 713 at the beginning and 711 at the close of the year, and there had been 126 admissions, sixty-four discharges, and sixty-four deaths. The voluntary patients had numbered 274 at the beginning of the year; there had been 170 admissions, while 131 had left and thirty-five had died; of the 444 under treatment during the year, only one had had to be certified. The mean age of the 228 patients admitted had been 46.2 years, the youngest being a boy of 10 and the oldest a man of 94. Three-fifths were in the middle period of life, one-fifth below 30, and one-fifth above 60. Fifty-four patients were engaged in professional occupations, twenty in commercial, twenty-three in industrial, and twenty-nine in agricultural; ninety-three females were engaged in domestic work, and nine other patients had no occupation. With regard to causes, pathologic stresses, including disease in such forms as general debility, exhaustion, malnutrition, heart and vascular disease, and glandular disease, were found in nearly all cases, including especially influenza in 8 per cent. and organic brain disease in 5 per cent. Biologic stresses were found in some 60 per cent., including the climacteric in 25 per cent., adolescence in 20 per cent., and senility in 12 per cent. Psychic stresses comprising emotional conditions such as worry, grief, and anxiety were found in 44 per cent., and hygienic and toxic stresses each in some 10 per cent. The types of mental illness among the admissions comprised chiefly the constitutional psychoses such as melancholia, schizophrenia, mania, and delusions in about 87 per cent., psychoneuroses such as epilepsy and neurasthenia in 3 per cent., and organic and congenital psychoses each in about 4 per cent. At the time of admission the patients had been mentally ill for less than six months in 54 per cent., up to two years in 22 per cent., and for upwards of two years in 24 per cent. Of the 195 discharges in 1933, 131 were voluntary patients and sixty-four certified. Of the voluntary patients, seventy-two left recovered, fifty-one improved, and eight unimproved, the recovery rate being 42.3 per cent. of the admissions. Of the certified patients forty-seven were recovered, sixteen improved, and one unimproved, the recovery rate being 37.3 per cent. The mean age on recovery was 42.2 years. Sixty-four of the ninety-nine deaths occurred in certified patients and thirty-five in voluntary ones. The death rate was 9.2 per cent. of the average daily number under treatment in the case of certified patients and 12.2 per cent. of voluntary patients. The chief causes of death were heart disease and arteriosclerosis 24 per cent., senile decay 13 per cent., cerebral arteriosclerosis and apoplexy 12 per cent., exhaustion 9 per cent., influenza with pneumonia 8 per cent., tuberculosis 6 per cent., bronchopneumonia 5 per cent., and epilepsy and general paresis 4 per cent. each. The mean age at death was 62.5 years, the youngest being 16 and the oldest 95, and the types of mental illness among those who died were chiefly dementia, melancholia, and delusional and confusional psychoses.

Edinburgh Dental Dinner

Proposing the toast of "The Edinburgh Dental Students' Society," at the annual dinner on February 9th, when Mr. Angus Millar presided, Dr. William Guy said that the modern education of the dental student was one of the most liberal that a man could have, and was directed towards making him a scientist, a craftsman, an artist, a

philanthropist, and a soldier in the great army which waged unceasing warfare against disease, ill-health, and deformity. Professor Sydney Smith, dean of the Faculty of Medicine at Edinburgh University, in proposing the "Edinburgh Dental Hospital and School," said that up to 1900 the dental profession had been mostly concerned with mechanical and manipulative measures. To-day dentists were mainly concerned with conservation—with keeping a healthy mouth and healthy teeth—and he expected that in the future a great deal of their activities would be directed to research in regard to nutrition, metabolism, and similar matters. Mr. Hutchison, dean of the Dental School, in replying, said that those who practised dentistry must now have both a liberal education and efficiency. These might be secured by having special classes in all dental subjects for dental students; by ensuring the efficiency of technical instruction through the appointment of heads of departments who would be at the hospital every day; and by the establishment in the universities and medical schools of chairs in dental surgery, from which dental education would be supervised and research work and post-graduate instruction encouraged.

Care of Crippled Children

The first published report of the Princess Margaret Rose Hospital for Crippled Children at Edinburgh, formerly known as the Edinburgh Hospital for Crippled Children, deals with the early activities of this institution. As a result of conferences held in 1926 and 1927 under the chairmanship of the Lord Provost of Edinburgh, it was decided to build a central orthopaedic hospital on the outskirts of Edinburgh with associated major clinics in the more populous centres of the south-eastern counties of Scotland, and minor clinics in the more remote and less populous parts of these counties. The scheme met with a ready response, and sums amounting to approximately £99,000 had been received up to March 31st, 1933. The hospital was opened to patients on June 1st, 1932, and in the first ten months forty-three patients were admitted. Steps were also taken to establish clinics in Edinburgh and at convenient places in the surrounding counties. A charge of £2 15s. per week is made for private patients, which is the estimated figure required to meet ordinary expenditure when the seventy-five beds in the hospital are full. In the case of patients sent by local authorities the charge is limited, in view of the present financial stringency, to £2 5s. per week. Until the hospital is full the committee of management have found it necessary to make an appeal for subscriptions, but it is expected that this will not be necessary when all the seventy-five beds are occupied. The administrative buildings and general layout have been so arranged to permit ready extension to 150 beds when necessary. The Duchess of York has taken the greatest interest in this hospital, and, following a visit which she paid last November, the Duke and Duchess have graciously consented to allow the institution to be named the Princess Margaret Rose Hospital for Crippled Children.

Assistance for Incurables in Glasgow

Speaking at the annual meeting of the Association for Relief of Incurables in Glasgow and the West of Scotland, Sir James Macfarlane mentioned that the association had now entered on its sixtieth year. In 1933 the number of patients under care in Broomhill Home was 150, in Lanfine Home sixty-eight, and on the roll of the outdoor relief department 128, making a total of 346. The ordinary income for the past year had been £16,093, as compared with £17,672 in 1932. There had been a deficit of £2,300, but the capital income for 1933 had been £5,134, which was an increase of £2,085 over that for 1932. The annual subscriptions for the year had been £1,964, which was £116 less than in 1932.

Reports of Societies

CONDITIONS COMMON TO OPHTHALMIC AND DERMATOLOGICAL PRACTICE

A joint meeting of the Sections of Ophthalmology and Dermatology of the Royal Society of Medicine was held on February 9th, under the chairmanship of Mr. E. W. BREWERTON, to discuss conditions common to both branches of practice. The discussion was limited to styes, rosacea, blepharitis, and one or two other conditions.

Mr. J. H. DOGGART said that the common ground between these two branches of medicine was extensive. There were many diseases in general medicine which commonly implicated the skin and eyes. Measles caused conjunctivitis, and possibly corneal ulcer, as well as a rash. Thyroid deficiency had been known to produce multiple opacities in the corneal substance. The eyeballs needed the protection of the lids, which were covered with facial skin, and certain neoplastic and inflammatory conditions of the skin—for example, rodent ulcer and lupus—showed a predilection for the face. In a few diseases, such as rosacea and pemphigus, the investing membranes of the eyeball itself might undergo damage. Styes often appeared to result from conjunctivitis or some other local eye condition, but in many other cases they were associated with pustules elsewhere, and were an expression of lowered general resistance to staphylococci. On the other hand, styes were often seen during a spell of good health and in the absence of any conspicuous local infection. Crops of them might last for months. A good many different substances had been tried in the way of treatment, by the mouth and hypodermically. In this country perhaps the autogenous vaccine had the best reputation amongst ophthalmic surgeons, but it was not at all certain to help.

Blepharitis was often divided, arbitrarily, into the mild or squamous and the severe or ulcerative types, but he doubted whether that division was of any value. In the great majority of cases blepharitis at its onset was probably due to some variety of conjunctivitis, or facial dermatitis. Frequently, however, long-continued blepharitis was seen in the absence of any conjunctivitis, and unassociated with any obvious disorder of the skin of the face. These cases, which were relatively far more common in hospital than in private practice, were often attributable to neglect or improper treatment in the early stages. Many patients got into the habit of rubbing the affected skin as a result of hot, irritable sensations, and so caused spread and prolongation of infection. The longer the condition went on the more the blepharitis would approach the ulcerative form, which was characterized by scantiness and irregular growth of the eyelashes. Many of these cases were aggravated by over-treatment. Normal saline was probably as good as most agents. The accumulated crusts should be sponged away by clean wool applied in the direction of the lashes. Application of ointment to the lid margins before sleep was useful, but sometimes the skin became so sodden and fissured by repeated wetting with lotion that it did more harm than good, and it was better to withhold it for a while to enable the skin to recover. He thought the aetiological importance of refractive errors was greatly exaggerated as the cause of blepharitis.

As for rosacea, in the mind of the lay public this remained inseparable from alcoholism, but most medical men now knew that abstinence was no guarantee against rhinophyma. Indeed, one variety was said, in an old work, to arise from excessive water-drinking, and to be curable by wine. Many writers conveyed the impression that ill-health was always associated with the condition, and it could not be denied that a large proportion of patients suffered from indigestion and other troubles. As to the relative frequency of ocular complications, the ophthalmic out-patient department gave a false idea of frequency, rosacea keratitis being an obstinate disease, tending to relapse, and many patients went from clinic to clinic. Nearly every case of rosacea in time developed a

mild blepharitis. Rosacea conjunctivitis was accompanied by a great deal of watering of the eyes and intolerance to light. Some cases displayed small nodules on the ocular conjunctiva near the corneal margin. Except in the mildest cases rosacea conjunctivitis signified impending keratitis, the earliest manifestations of which consisted of vascular loops invading the edge of the cornea. Rosacea keratitis was a very serious handicap; a bad case might relapse many times a year, so as to incapacitate the patient from doing regular work. Although severe keratitis might result in scanty signs on the face, yet in any particular case it was usual to find a close correspondence between corneal and facial outbreaks, in the sense that fresh infiltrates in the eye seldom occurred in the absence of renewed skin activity. Therefore it was unreasonable to expect a permanent cure for rosacea keratitis unless the skin lesions could be prevented from recurring. The frequency and severity of the attacks would often decline with the approach of old age, but meanwhile the cornea might have become entirely opaque.

Dr. H. C. SEMON, speaking on rosacea, said it was unknown in children, rare before 30, and more common in women than in men. It affected women especially at the menopause. Lesions were confined to the face; especially the malar prominences, the forehead, chin, and nose; the last-mentioned was sometimes, in the case of men, apt to be severely implicated, and to lead in time to a condition of extreme sebaceous hypertrophy. The almost invariable association of flushing, either post-prandial or emotional, strongly suggested vasomotor instability, which in part explained the tendency of the disease to appear at the menopause. Chronic congestion led ultimately to a varying degree of paralytic distension in the vessels of the corium and infection of the sebaceous glands, with clinical evidence of this in the appearance of papules and pustules in the "flush area." This also included the scalp, and most cases presented evidence of its implication in increased tendency to greasiness and scurf. The area of involvement almost exactly corresponded with that of the fifth nerve distribution. In spite of its comparative frequency in dermatological practice, rosacea rarely presented eye lesions in the out-patient department. He had never yet had to refer a case to the ophthalmological department, though many had been referred to him from that source for treatment. Although dyspepsia was not always apparent, hypochlorhydria was a presumed cause or association in a considerable number of cases, and hydrochloric acid was a useful adjunct in the treatment, which must also include attention to the teeth, tonsils, and other sources of focal sepsis, and strict adherence to a simple and non-stimulating type of diet. Tea was a more common factor in the production of rosacea than alcohol. Local applications of weak sulphur or ichthyol lotions relieved the subjective symptoms, and checked the tendency to septic complications. X-ray treatment was seldom required, and by no means always successful. Other irradiations were useless, and sometimes harmful.

Turning to dermatitis of the eyelids, Dr. Semon said that this might be either primary or secondary; usually it was the latter. It might occur at any age, but was not common in childhood apart from conjunctivitis. Most cases were due to an external (exogenous) cause. The causes, of which any number were possible, included substances to which the patient had an acquired or hereditary idiosyncrasy, such as dyes, hair, or fur; plants such as primula, chrysanthemums, and narcissus; and scents, such as *orris root*, employed in face powders. Dermatitis of the face might be preceded by swelling and irritation of the eyelids. The diagnosis of dermatitis of the eyelids was always easy, but the cause, on which prognosis and treatment depended, was seldom apparent, and might result in many recurrences before discovery led to prevention and cure. As a secondary complication of seborrhoeic infection, dermatitis of the eyelids was exceedingly common, and from the dermatological aspect mainly occurred in two forms—namely, simple swelling, with or without a yellowish superficial infiltration, and marginal blepharitis. The persistence of blepharitis and the coincident loss of lashes appeared to offer a guide in the matter of prognosis. The treatment of this form of

dermatitis was that of the underlying seborrhoeic state or diathesis, the exact cause of which had still to be discovered. As for styes, the index references of the leading dermatological textbooks ignored the term, and the condition was only treated by dermatologists when it was part of a general furunculosis or a complication of the seborrhoeic state. Most dermatologists would hesitate to define the differences between styes (hordola), chalazion, and meibomian cysts, and the majority would, if they were wise, refer their cases to the proper quarter.

Mr. R. A. GREVES said that some years ago he had the temerity to publish a paper about the treatment by x rays of acne rosacea, and since then he had been overwhelmed with cases. He had quite a large clinic at Middlesex Hospital of acne rosacea cases with ocular manifestations. Corneal lesions were by far the commonest, but usually occurred as single or local infiltrates in the superficial layers of the cornea. The overlying epithelium broke down, and an ulcer formed. The cases were extremely resistant to treatment, and when healing took place an appreciable amount of scarring was left. These lesions almost invariably kept on recurring, and a wide area of cornea became involved. A less common variety began with inflammation at the corneo-scleral junction. The most characteristic feature of the disease was its obstinacy and the repeated appearance of fresh lesions, whether the old ones were healed or not. As regards treatment, acne rosacea was a manifestation of some constitutional disturbance, and the logical method would be to correct this if possible. As for local treatment, he found that the eye lesions responded best to stimulation, and for this reason he prescribed hydrochloric lotion as a stimulant, and yellow oxide of mercury ointment, with, of course, atropine, which relieved pain and photophobia. It was a mistake to cover the eye with a pad, but dark glasses gave relief. The greatest good was done by x-ray applications, between one-sixth and one-third of a Sabouraud pastille dose being given. Applications should not be made more often than once a fortnight. X rays might cause a recent infiltrate to disappear. This treatment also had the result of relieving pain, which was so distressing a feature of the condition. Fresh attacks were almost bound to occur if the constitutional cause persisted, but the interval between recurrences was lengthened by this treatment. He had never seen any harmful results follow from x rays, and there was no visible reaction with so small a dose.

Dr. SYBIL EASTWOOD said that for some years at University College Hospital she had had the opportunity of tackling the problem of rosacea from the point of view of the general physician. It had been said that the digestive factor in rosacea was overrated, but after seeing a series of several hundred cases she had found some digestive disturbance in 95 per cent. of them. It was often comparatively mild, but the underlying factor of the rosacea with ocular complications and pustules was vascular congestion of the face, which was probably a reflex from some other part of the body, and in very many cases the stomach. It was often assumed that hydrochloric acid was the only thing which counted in producing this reflex dilatation of the vessels, but this was by no means the case. Roughly, 48 per cent. of cases of rosacea had either achlorhydria or very low curves, about 40 per cent. were completely normal, and about 10 per cent. had a high curve. The most promising cases were those with low hydrochloric acid secretion. These, if given hydrochloric acid, became, comparatively speaking, well, the period of remission lasting, perhaps, for as long as five or six years. But some cases with pyloric spasm and very high acidity curves had been equally amenable to proper treatment. She thought that some of the failures had been due to attempts to treat these people by giving them acids or alkalis without trying to find out in each case individually whether acid or alkali was needed. Quite a number of patients did well if given acid with meals, followed by alkali one and a half to two hours later, so as to produce the normal cycle of digestion. She agreed that alcohol was not a very big factor in production; over-drinking of tea and excessive starch consumption were more frequent causes. Dr. Semon had said that the condition was more common in women

than in men. In her view it was about the same in both sexes, but the aesthetic consideration weighed more strongly with women in causing them to come for advice and treatment. If the problem were treated, neither as a dermatological nor as an ophthalmological one, but as a general medical problem, in which the objective was to restore the patient's general health to normal, recurrences would be fewer and the condition would fade out altogether.

Dr. S. H. BROWNING said that quite a number of people were sent to him for bacteriological examination of the eyelid, and he found them suffering very badly from seborrhoea of the scalp; their blepharitis would get well if treatment started with the scalp, coming downwards if necessary. Most of the blepharitis he saw was due to the staphylococcus, either the *albus* or the *aureus*, and here vaccines were useful adjuncts to the other eye treatment. Very shortly an anti-staphylococcus serum would be available for the treatment of styes and acute staphylococcal conditions more efficiently than hitherto. With recurrent styes anti-staphylococcal vaccines were valuable, but some cases did not get well with these vaccines: these patients, he thought, had a streptococcal infection. In treating staphylococcal conditions, boils or styes, he had found quite large doses of hydrochloric acid, three or six times a day, with plenty of water, very effective.

The PRESIDENT (Mr. BREVERTON) asked whether there was any danger in operating on a styte at an early stage. It was very tempting, if the patient was having a bad time, and the styte was actually pointing, to incise it. What was the risk of spreading infection along the line of the needle? One heard, occasionally, of catastrophes. Mr. EUGENE WOLFF said that Dr. Semon had told them that probably the eye and the skin were affected together, because they had the same sympathetic supply, and Mr. Doggart had shown pictures in which the lower part of the cornea was affected. So far as the speaker was aware, there was no difference between the sympathetic supply of the corneal vascular plexus above and below. One wondered, therefore, how far exposure played a part in the production of acne rosacea lesions in the eye. Mr. JOHN FOSTER said that apparently on the Continent it was not uncommon to treat blepharitis by exposing it to x rays, but there was a prejudice against it in this country and in America on the ground of possible damage to the eye. Had any dermatologist present treated it in that way? Dr. A. C. ROXBURGH replied that he had treated a number of cases of chronic blepharitis with small doses of x rays, and they had all improved—some might be said to be cured—but he would not like to say that it was an entirely reliable method, though he had never seen any trace of damage to the lens.

PROBLEM OF THE DIPHTHERIA BACILLUS

At a meeting of the Fever Group of the Medical Officers of Health Society on January 26th, with the president, Dr. H. S. BANKS, in the chair, Dr. WILLIAM MAIR read a paper on varieties of *C. diphtheriae*.

Dr. Mair classified diphtheria bacilli on the separation of (1) the barred group, which does not ferment starch and which is highly characteristic in its morphology, mode of growth, and reaction in the guinea-pig, and (2) the starch fermenters, the morphology of which is not so characteristic, from (3) the remaining strains, which he regards as a miscellaneous group. With lantern slides illustrating these points, and statistics based on several thousand cultures, he showed that there has been an increase in the barred and starch-fermenting strains in London in recent years, and that these strains are now associated with the more severe cases of diphtheria. The subsequent discussion made it clear that Dr. Mair's barred form corresponds exactly to the "intermediate" form, the starch fermenters correspond to the "gravis" group, and the miscellaneous group includes the "mitis" and "atypical" groups of the Leeds workers.

Dr. ALEXANDER JOE gave the results of 192 cases which he had classified clinically and in which Dr. Mair had typed the organism. Cases in which starch-fermenting

organisms were found numbered fifty-three, and showed a paralysis rate of 20.7 per cent. and a case fatality of 11.3 per cent.; eighty-four cases in which barred forms were found showed a paralysis rate of 23.8 per cent. and a case fatality of 8.3 per cent.; while in the non-fermenting group of fifty-five there was a paralysis rate of 9.1 per cent. and a case fatality of 5.6 per cent. Dr. Joe pointed out that his cases were not consecutive and that the series contained a higher proportion than normal of severe and moderately severe cases, but otherwise he thought the cases were representative. While being cautious about the statistical interpretation of his results, he believed they gave some support to the observations of the Leeds workers, and referred to the interesting behaviour of diphtheria in London, which at present, in the view of most of his colleagues, was tending to become more severe. If this tendency should become more marked it would be of the utmost importance to note whether starch-fermenting organisms became predominant.

Dr. J. S. ANDERSON referred to the combined statistics of Leeds, Hull, Manchester, and the North-Western Hospital, London, in all of which centres bacteriological and clinical results had been correlated. Exception had been taken to the nomenclature of the types, but in view of these statistics the Leeds workers continued to uphold their attitude. It was pointed out that, in the original papers, the possibility of intermediate strains approaching gravis strains in virulence had been foreseen. The criticism that the association of severe diphtheria with gravis strains was a local phenomenon was now obviously untrue, as a similar state of affairs existed elsewhere. Delayed treatment and inadequate treatment as factors could likewise be set aside. Dr. Anderson restated the view that endemic diphtheria might be caused by mitis strains and epidemic diphtheria by gravis and intermediate strains, and also referred to the work of Povitsky, Eisner, and Jackson in New York, in which it was suggested that gravis strains possessed a greater invading power and produced toxin in the human body more rapidly than other strains. He drew the attention of clinicians to the marked decrease in the incidence of laryngeal disease in Leeds, and to the marked increase in the case mortality between the ages of 5 and 10 years, both being features of a severe epidemic in which gravis strains were predominant. He asked for more observations to be made in both these directions.

Professor McLEOD remarked that, if the cases brought forward by Dr. Mair and Dr. Joe were taken into account the bacteriological type and the clinical condition had been correlated by now in 2,000 cases from fever hospitals situated in Dundee, Glasgow, Hull, Leeds, London, and Manchester respectively. Of these 45 per cent. were of the gravis type with a 13.6 per cent. case mortality; 35 per cent. of the intermediate, with a 10.5 per cent. case mortality; 17 per cent. of the mitis, with a 3.2 per cent. case mortality; and 2 per cent. of the atypical, without recorded death. These facts, together with the observation that infectivity of the pellicle-forming and starch-fermenting strains seems to be greater, appeared to justify the adoption of the name gravis for these strains. Although, Professor McLeod continued, the evidence in support of this view from animal experiment was less frank, it was clear that there also the gravis strains were more formidable. On the average they killed the animals more rapidly, they persisted more frequently in the tissues, and, further, non-pathogenic strains were so rare that tests for pathogenicity with characteristic strains of this type appeared to be superfluous. On the other hand, although highly pathogenic strains of both intermediate and mitis types were common, from 5 to 15 per cent. of the total number examined had been found to be non-pathogenic or relatively apathogenic for animals. An unusual type of starch-fermenting strain had been met with in Glasgow in small numbers. These strains were unlike the usual gravis strains, both in respect of the appearance of the colonies and of the characters of their growth in broth. With the exception of a few strains less definitely smooth in broth cultures they had been found to be non-pathogenic to animals. It was an interesting speculation

whether these strains might prove to be the reservoir from which an epidemic of severe diphtheria might presently be developed in Glasgow.

Of the eight mitis deaths in this series observed outside London all but one—from an infant who first received treatment on the seventh day of disease—had been complicated by tracheal obstruction, bronchopneumonia, or severe enteritis. Primary toxic deaths, such as occurred frequently in the intermediate and gravis cases, seemed to be extremely rare in mitis infection.

Dr. R. A. O'BRIEN said that diphtheria, which was virtually a preventable disease, still caused many deaths. They therefore owed much to the Leeds workers for stimulating valuable research on typing. He looked forward to studying in detail, when they were published, the figures presented at the meeting. So far as he knew diphtheria antitoxin used prophylactically had never failed to stop an outbreak anywhere in the world. Obviously, therefore, all types of the diphtheria bacillus must be, immunologically, closely related, if not identical.

Surgeon Captain SHELTON DUDLEY said that in the Royal Naval Medical School trypsin serum agar gave a cleaner-cut differentiation of the three types of Klebs-Löffler bacillus colony than the Leeds workers' chocolate medium. The colony morphology could, however, be distinguished on many media, including plain ox-heart agar. Miss Orr Ewing had shown that the starch-fermenting gravis strains of K.L.B., which were received from different places, fell into several serological groups—a fact which to some extent harmonized the discordant reports on the cultural and pathogenic characters of gravis K.L.B. In a school where diphtheria had been endemic for years artificial immunization was successful in keeping the school free of the disease for four years, though carriers of virulent K.L.B. remained plentiful. In October, 1932, a gravis type of K.L.B., of the same serological group as that predominant in Leeds appeared for the first time in this school. Synchronously with this event an epidemic of mild modified diphtheria broke out in this fully inoculated population, and the carrier rate for K.L.B. was higher than had ever been noted before. This observation was consistent with the view that this serological type of gravis *C. diphtheriae* was more infective and invasive than the average. In his opinion the school had only been saved from a much more severe and wider spread epidemic by the fact that it had been inoculated against diphtheria. The cases which occurred in these partly immune subjects were trivial and mostly unrecognizable as diphtheria without laboratory confirmation. It was, however, very uncertain how far other serological groups of gravis *C. diphtheriae* deserved the name on clinical and epidemiological grounds. The bacterial flora changed so frequently with time and place that it was doubtful if any classification, or correlation of bacterial type with clinical picture, which might hold to-day would have any permanence.

Dr. H. J. PARISH agreed that most strains now being isolated in London fell into the Leeds groups, although a year or two ago atypical strains were common. The organism was apparently in a constant state of flux, and, although severe diphtheria was to-day associated mainly with gravis in several areas, there was always a possibility that some new variant—or even the classical mitis strain—might cause a high mortality in future. Ewing showed that the Leeds gravis agglutinated differently from the Hull gravis. One could therefore doubt if direct spread had occurred.

Dr. STURDEE said that apparently severe outbreaks of diphtheria had been caused by both gravis and intermediate types. If at some future date a severe outbreak were found to be due to mitis they would be where they were. At any rate, there seemed no reason at present to advise a medical officer of health to alter in any way his procedure for dealing with diphtheria. It would be interesting if bacteriological investigation were made of some obviously mild outbreaks in order to see by what type of diphtheria organism they were caused. There might be danger in calling an outbreak severe if the day of disease on which antitoxin was given was not known.

LOWER SEGMENT CAESAREAN SECTION

At a meeting of the North of England Obstetrical and Gynaecological Society, held at Manchester on January 26th, with the president, Professor DANIEL DOUGAL, in the chair, Dr. K. V. BAILEY (Manchester) read a paper on the lower segment operation as the routine Caesarean section.

He said that the operation should be performed in all cases in which abdominal delivery was thought to be necessary, whether the patient was in labour or not, and whether she was potentially infected or not: he claimed that it was a safer procedure, with a smoother convalescence and a sounder ultimate result, than the classical operation. Though the lower segment was only fully developed after labour had begun, the part of the uterine wall through which the incision was made was thinner than it was at a higher level, even before labour. It was therefore permissible to speak of the lower segment operation, even when it was carried out before the onset of labour. In his own series of cases, he continued, fifty-one were in labour and fifty-eight were not. Without giving a full description of the operation, Dr. Bailey stressed the following points in technique.

He preferred, he said, the horizontal position to any form of Trendelenburg position. Even a modified Trendelenburg position might embarrass the breathing owing to the fundus uteri falling against the diaphragm and so, rendering the administration of anaesthesia difficult. The weight of the uterine body pulling on the lower segment increased the liability of the incision to split during extraction of the child. In the Trendelenburg position the extraction was made more difficult by being carried out uphill; more force was required than in the horizontal position; also, potentially infected liquor and blood tended to flow downhill into the upper abdomen, however well the swabs were disposed. A sub-umbilical incision was made; then the sides of the abdominal cavity were packed in the usual way, and a retractor (Doyen or self-retaining separator) was introduced at the lower end of the wound. The lower segment was incised. Dr. Bailey favoured a semicircular incision, the mid-point being a quarter of an inch above the bladder reflection, and the ends pointing directly upwards, parallel to the sides of the lower segment. He considered that it gave the best access with the maximum of safety. A vertical incision had been followed by fatal rupture into the bladder, and a transverse incision might split during extraction of the child, with serious haemorrhage from the uterine vessels. He incised and reflected the peritoneum before dealing with the muscle. The hand of the operator which was nearer to the patient's feet was then introduced through the incision and passed to the back of the child's head. The other hand retracted the upper flap of the uterine incision, and the assistant pressed firmly and uniformly on the fundus. Thus the head was shelled out and the body subsequently delivered. During this manoeuvre, Dr. Bailey said, the excellent access given by the type of incision described could be appreciated. He had never found the forceps necessary. He did not like the idea of using a somewhat unwieldy metal instrument inside a thin-walled space, and preferred to use his lower hand as elevator and guider. Next, the uterus was lifted out through the abdominal incision and compressed between warm swabs. The placenta was expressed by this means, combined with traction on the membranous surface. He deprecated the insertion of the hand into the uterus as being a possible source of sepsis. The uterus was sutured with two layers of continuous chromic catgut No. 2, the first including the endometrium and half of the muscle, the second the other half of the muscle and the peritoneum. In potentially infected cases the second suture did not include the peritoneum, which was stitched separately with a third suture. The retractor and swabs were removed, the abdomen and pelvis were freed of blood, and the abdominal incision was closed.

In the series of 109 cases there had been no maternal death. Fifty-eight patients had been operated on before labour, in good condition. Of the fifty-one in labour, fifteen had been in labour more than eighteen hours, and in eight the membranes had been ruptured more than ten hours. In nine the time in labour had been between thirty-two and seventy-two hours, and the pulse had been high before operation. In nine cases the placenta had partly occupied the lower segment, and in one there had been ante-partum haemorrhage because of this. There had been two cases of concealed accidental

haemorrhage and one of eclampsia. Twenty-one cases had been morbid; the standard of morbidity was fever reaching 100° F. on at least two consecutive days after the third post-operative day. Of these cases eight had chest, four urinary, and two breast infections. A reactionary temperature of 100° or more occurred in twenty-one cases during the first forty-eight hours after operation. Six of the babies had been stillborn (two concealed accidental haemorrhage, one maternal valvular disease, one hydrocephalus and spina bifida, and one asphyxia), and one had died on the second day (placenta praevia). The infant mortality of the series was 6.4 per cent.

Summarizing his views on the operation, Dr. Bailey said that he believed, from a consideration of the literature and from his own experience in the three cases in which he had done a second lower segment operation on the same patient, that the risk of rupture of the scar must be much less than in the classical operation. In his three cases the uterine scar at the second operation had only shown as a slight puckering of the peritoneum. The operation was rather more difficult than the classical procedure, and should only be undertaken by the experienced gynaecologist.

RECOVERY IN NON-MENINGOCOCCAL MENINGITIS

At the seventh annual meeting of the Association of Clinical Pathologists, held in the Inoculation Department, St. Mary's Hospital, on January 27th, with Professor A. FLEMING in the chair, Dr. S. C. DYKE (Wolverhampton) opened a discussion on the prognosis and treatment of meningitis other than that due to tuberculous or meningococcal infection.

Dr. Dyke said that he had been struck by the difference in opinion which appeared to exist as to the gravity of the outlook in meningitis of pneumococcal, staphylococcal, or streptococcal origin. His own experience had been that, once any of these organisms had been isolated from the cerebro-spinal fluid, death invariably followed. The records of the Royal Hospital, Wolverhampton, for the past four years showed that death had occurred in all cases (twenty-seven) of meningitis in which Gram-positive cocci—in eighteen cases pneumococci, in six streptococci, and in three staphylococci—had been isolated from the cerebro-spinal fluid. He had frequently been told by others of cases of bacteriologically proven infection by these organisms in which recovery had ensued. With the view of obtaining some light on the subject a questionnaire had been issued to all members, and the following cases represented the response. Dr. Dyke stated that he himself had had experience of only one case of recovery in meningitis not meningococcal. In this the infecting organism was a haemophilic bacillus of the Pfeiffer type. The patient was a male, aged 22, in whom lumbar puncture had been performed twelve times in sixteen days.

Dr. J. HARWOOD LITTLE (Chichester) reported a similar case in a boy aged 8. The source of infection was apparently the ear, and lumbar puncture was performed only once, a bacillus of the Pfeiffer type being isolated. Dr. CUTHBERT DUKES gave brief notes of a case in which haemolytic streptococci had been found in the cerebro-spinal fluid. One week after the onset anti-scarlatinal antitoxin had been injected intrathecally and intravenously on successive days, with subsequent recovery. Dr. G. W. GOODHART, in absence, forwarded the report of one case in which recovery had ensued after isolation of streptococci from the cerebro-spinal fluid. Lumbar puncture had been performed four times. Dr. ELIZABETH O'FLYNN recorded recovery in a case of mixed meningococcal and streptococcal (haemolytic) meningitis. The following cases of meningitis in which recovery took place were also reported: Dr. A. G. SHERA (Eastbourne), a case of fracture of the skull involving the ethmoids in which *Streptococcus viridans* had been found in the cerebro-spinal fluid; Dr. F. B. SMITH (Preston), a case due to

haemolytic streptococci; Dr. D. S. MURRAY (Richmond), a case due to *Staphylococcus aureus*; Dr. I. B. MORRIS, a case in which *Staphylococcus albus* had been isolated from both the blood and the cerebro-spinal fluid.

Dr. J. G. GREENFIELD referred to instances in which pus found on lumbar puncture came not from the theca, but from the epidural space. In such cases repetition of the puncture carried with it the danger of infecting the meninges. Dr. EMBLETON put in a plea for frequently repeated puncture in all cases of meningitis. He did not consider every six hours too frequent. Dr. GREENFIELD made mention of drainage of the theca by an indwelling lumbar puncture needle cut off and bent over a perforated metal plate. Dr. DYKE pointed out that the evidence went to show that isolation of Gram-positive cocci from the cerebro-spinal fluid in cases of meningitis although it rendered the prognosis grave in the extreme, evidently did not justify the abandonment of all hope.

Dr. R. MAEGRAITH (Oxford) described a precipitin reaction for the diagnosis of cerebro-spinal fever. The reaction consisted in bringing together in Dreyer's tubes small amounts of cerebro-spinal fluid as antigen and a suitable anti-meningococcal serum as antibody. A positive reaction was shown by the appearance of a white precipitation ring at the juncture of the two fluids. The reaction became positive within the first few hours after the onset of symptoms, and constituted a valuable aid to early diagnosis.

Miscellaneous Communications

Professor G. S. WILSON, in a communication on the diagnosis of *Brucella abortus* infections, said that abortus infection in this country was practically always due to the bovine type, which in primary culture requires an atmosphere of 10 per cent. carbon dioxide. The bovine type had high infectivity but low pathogenicity; many persons whose work brought them in contact with cattle developed serum agglutinins against the organism without ever having had symptoms of the disease. The mere demonstration of agglutinins in the serum was therefore not proof of the existence of the disease. For diagnosis, either a high agglutinin titre or characteristic symptoms were requisite. In persons not exposed to infection a diagnosis might be permissible on a low agglutinin titre, but this was not permissible in those exposed to infection unless the clinical picture was typical. Blood culture formed a valuable method of diagnosis. The best culture medium was 1 per cent. glucose broth, and incubation should be prolonged in an atmosphere of 10 per cent. carbon dioxide.

Dr. H. J. PARISH spoke on staphylococcal toxin and toxoid, with special reference to the use of the latter as an immunizing agent. The anti-staphylococcal haemolysin titre of the serum rose, he said, *pari passu* with the antitoxin value. Both in men and in animals the anti-haemolysin titre could be greatly increased by injections of toxoid, and he described a simple technique for the estimation of the anti-haemolysin titre of the serum, drawing particular attention to the value of this procedure as a means of estimating the response to immune therapy, either passive by means of serum or active by means of toxoid.

Dr. E. L. STURDEE detailed the results of a statistical inquiry into the therapeutic effect of anti-meningococcal serum. Allowing for the fact that reliable controls were extremely difficult to secure, he said that by the use of serum the mortality rate had been reduced by from 20 to 30 per cent. Dr. W. M. SCOTT pointed out that the type of meningococcus predominant in the present epidemic area was I-III, as opposed to the state of affairs in the epidemic period 1915-19, when the II-IV type was mainly met with. Dr. R. A. O'BRIEN spoke of the debt which those concerned with the manufacture of therapeutic serum owed to the work of the medical officers of the Ministry of Health. He deplored the absence of any reliable test as to the therapeutic efficiency of anti-meningococcal serum; the agglutinin titre he regarded as a very doubtful criterion of therapeutic value.

VACCINATION: THE PRESENT POSITION

At a meeting of the Medical Society of London on February 12th, with Sir JOHN THOMSON-WALKER, the president, in the chair, a discussion was held on "The Present Position of the Vaccination Question."

Dr. C. KILLICK MILLARD said that thirty years ago he read a paper before the Society of Medical Officers of Health which got him into some disgrace with his particular branch of the profession. A senior member of the society said that such a paper ought never to have been read, and moved that it be not printed. A compromise was made by allowing the paper to be printed, but with no reference to the fact that it had been read before the society. The paper was entitled "The Leicester Method of Dealing with Small-pox." His suggestion that it might be possible effectually to control small-pox without recourse to compulsory vaccination caused great offence at that time. He did not think that now such a paper would cause very much disturbance. Nothing that had happened in the course of those thirty years had weakened his profound faith in the power of vaccination to confer protection, specific in nature, on the individual against small-pox. He knew of no other fact in the whole field of medicine more definitely established. But it must be understood that the protection was only temporary, even though it usually lasted for a period of years. An important distinction was to be drawn between the effect of vaccination on the individual and on the community, and its protection for the community was not nearly so well established as its protection for the individual. In the past there had been too much readiness to regard the reduction in small-pox mortality which followed the introduction and increased use of vaccination last century as necessarily all due to vaccination. As an example, he referred to a table given by the Registrar-General in his annual report for 1880, in which three periods were taken and contrasted as regards vaccination and small-pox mortality:

Periods	Vaccination	Small-pox Mortality
1847-53	Optional	305 per million
1854-71	Obligatory, but not efficiently enforced	223 "
1872-80	Obligatory, and more efficiently enforced	155 "

Many authorities had quoted this table with approval as vindicating vaccination. How little they foresaw what the future years would reveal! If the table were carried forward on similar lines it would show a great decrease in vaccination, the introduction of a conscience clause, the making of exemption easier by allowing parents to make statutory declarations, and, finally, a state of affairs in which more than half the children born remained unvaccinated, and yet, parallel with this, small-pox mortality had gradually fallen and was now at vanishing-point. There was no true relationship between the amount of infant vaccination and the mortality from small-pox; other and more important factors must have been at work. Here Dr. Millard compared the experience of England, where sanitation had made so much progress, with that of India, where sanitation was backward. For generations small-pox had been a scourge in India, in spite of an active vaccination and revaccination service. In India the amount of vaccination per million of population was much greater than in this country, but, on the other hand, the small-pox mortality, instead of declining, remained at an appallingly high figure. During the last twenty years the deaths in British India from small-pox showed no decrease at all. During the quinquennial period 1911-15 there were 405,000 deaths, and during the last quinquennial period, 1926-30, there were 477,000. Such an appalling death rate indicated the tragic failure of preventive methods, including the system of vaccination. He would admit that if every one of the hundreds of millions of the Indian population was recently vaccinated and kept recently vaccinated, small-pox deaths would cease, but such an ideal course was even less attainable there

than in this country. There had been similar failures of vaccination in England in towns where infant vaccination was unsupported by other methods of sanitation. He instanced the case of Middlesbrough in 1897-8, a town in which the proportion of vaccinated children was very high, but which, in the words of its medical officer at that time, was "the home of epidemics"; there a serious small-pox epidemic took place, and 86 per cent. of those affected were vaccinated persons, and 108 of those vaccinated persons died. The last visitation of Asiatic small-pox, variola major, in this country, occurred in the early years of the twentieth century. Since then there had been isolated outbreaks, but all had been successfully stamped out, in spite of increasing default in the matter of vaccination.

VARIOLA MAJOR AND MINOR

During the post-war period the whole situation had been radically changed. Variola major had virtually disappeared, and its place had been taken by a trivial form of small-pox—variola minor—non-fatal, not permanently disfiguring, and not much more serious clinically than chicken-pox. During the years 1922-33 there were in England and Wales 81,080 of these cases of variola minor; 254 deaths (0.3 per cent.) were ascribed to it, but probably in a majority of these deaths small-pox was only a secondary cause. Variola minor was a distinct entity, which for all practical purposes might be regarded as breeding true, and there was no satisfactory evidence that it changed into variola major. The two varieties of small-pox presented two different administrative problems. There was still a good deal of difference of opinion as to measures to be taken in dealing with an outbreak of variola minor. In practice, at the beginning of an outbreak, many medical officers of health were prepared to go considerable lengths, but later on they were less averse from a policy of *laissez-faire*. It was not unreasonable to ask what would happen if such a policy were really followed. Would the epidemics really behave like epidemics of chicken-pox? There would be this difference, that with respect to chicken-pox the population was largely protected by previous attack, but in time the same thing would obtain with regard to variola minor. If it did spread and were allowed to take its course that would be in some ways an advantage, and would go far to comfort those who were seriously alarmed at the great danger created by the neglect of vaccination. If variola minor protected permanently against variola major it would have an advantage over vaccination, which gave only a temporary protection. It might be worth while trying the effect of substituting for vaccination in India inoculation with variola minor. He believed that variola minor was not a new disease; it has existed in many parts of the world from time immemorial. In Leicester in 1904 there were 321 cases and only four deaths, and he believed those four deaths could be accounted for by an accidental introduction of variola major amongst the variola minor, which at that time was not recognized as such.

Another great factor which had profoundly modified the vaccination question was the occurrence and recognition of post-vaccinal encephalitis. Dr. Millard admitted that it was easy to exaggerate its importance, and the total number of cases which had occurred in proportion to the number of vaccinations performed was very small. On the other hand, it was possible to belittle this new and added danger attaching to vaccination—a danger which was greater when compulsory vaccination took place of unvaccinated contacts, especially between 5 and 15 years of age. He concluded by saying that in spite of steadily diminishing vaccination variola major had been practically banished from these islands for thirty years, and, notwithstanding importations favourable to its spread, had never succeeded in getting a foothold. They were always told that it might come back, but it showed less and less tendency to come back, and was now becoming an exotic. Variola minor was admittedly so trivial that it was difficult to justify compulsory vaccination, especially in view of the fact that vaccination could not be said to be an operation free from danger. It might be said that compulsion to-day was only nominal,

but if vaccination was not compulsory why hesitate about the abolition of the cumbersome machinery of compulsion? It was true that at the Representative Meeting of the British Medical Association in Dublin last summer a motion calling for the abolition of the compulsory element in vaccination was not carried, but he would suggest that general practitioners were less in touch with what might be called modern thought on this question than were the medical officers of health, on whom the task fell of having to combat small-pox should it arise.

NEED FOR FRESH LEGISLATION

SIR GEORGE BUCHANAN agreed that there was no doubt that the type of small-pox now in evidence had been breeding true, and that it could properly be called variola minor. At the same time they might always get variola major. Only a year ago he was passing through Alexandria and found there a typical outbreak of variola major, exactly of the same type as that with which he made acquaintance in this country for the first time in 1892. The same state of affairs obtained in many countries, and with facilities for importation, such as the increased use of aircraft, and so on, he would not like to say that this country was out of danger, though he thought that, barring accidents, if there were importation it could be very quickly brought within bounds. There was no doubt about the protective value of vaccination; it was true that it was temporary, though it lasted for a long time. He could not attach quite the same value as Dr. Millard had done to sanitation in general as a means of diminishing small-pox, unless in sanitation he included the detection and isolation of small-pox cases. He thought that the State or the local authority ought to provide facilities for vaccination, making it available to anyone of any age and at any time, though that did not necessarily mean that the present public vaccinator system must be kept up. Legislation in regard to vaccination was certainly overdue. The powers under the Public Health Acts were not sufficiently definite. Only one thing was an obligatory requirement—namely, infancy vaccination—and this was particularly ineffective as a means of controlling small-pox. The whole thing wanted re-drafting, but parliamentary time and organized opposition had to be considered. The extreme anti-vaccinator had been a great obstacle to progress, because he was not content with a number of good points which he could make, but went on to say that vaccination did not protect against small-pox, which made it difficult to take him seriously.

Dr. J. P. MARSDEN said that all would agree that a successful vaccination protected against small-pox for a limited time; most would agree that as a method of abolishing small-pox from the community compulsory vaccination as applied in this country was a failure. It always would be a failure in a community other than one subject to rigid discipline. For that reason, added to the fact that for many years in this country the only type of small-pox, with one or two exceptions, had been a small-pox devoid of mortality, there had arisen a demand for the abolition of the compulsory element in vaccination. Should this be left entirely to the individual? So long as vaccination remained compulsory, even if compulsion were not applied very efficiently, a certain amount of vaccination was carried out. He also drew attention to the new procedure in vaccination, following on the recommendations of the Rolleston Committee, whereby one insertion instead of the previously recommended four was made. That was a popular move, very quickly appreciated by the man in the street, but it was still a question how long such protection lasted. What evidence was available went to show that the larger the area and the greater the number of scars, the longer the protection. With regard to encephalomyelitis, that particular condition was not confined to its association with vaccination. A condition which, if not the same, was at any rate indistinguishable from it, might be found associated with small-pox. He had had under his care seven cases of encephalomyelitis which had followed attacks of small-pox. In the patients who died and were examined pathologically the histological picture was indistinguishable

from encephalomyelitis following vaccination. Therefore the argument that by abolishing vaccination one would abolish encephalomyelitis would not hold.

NOMENCLATURE OF VARIOLA MINOR

A good deal was heard of variola minor. This was small-pox which ran a modified course, the cases being due to infection with an avirulent strain of the virus. There was nothing new in that at all. The modification of an attack of small-pox, breeding true in a series, had been known to exist since Jennerian times. Outbreaks of small-pox had occurred in which there had been practically no mortality. Infection with an attenuated, avirulent, and benign strain of small-pox virus would produce an attack of small-pox which ran a modified course. But that was not the only factor which would produce such an attack. If a man who was relatively immune, either by virtue of a previous vaccination or some degree of natural immunity, came into contact with a virulent and malign strain of small-pox, his attack would be modified, and clinically it was not possible to distinguish between the two cases. Regarding the man as a unit, one could not say whether he was suffering from variola major, minor, or minimus. His objection to the term "variola minor" was that it was not a clinical term. One could tell by studying a series, and finding out whether the disease bred true, that it was variola minor which was concerned, but one could not tell it by looking at an individual patient. That was one of his main arguments against making a distinction in one's preventive treatment between so-called variola major and variola minor.

Dr. E. W. GOODALL disagreed with the last speaker as to the nomenclature of variola minor. If the medical profession had not invented a name for this disease the people of this country would have done so. Many such conditions had been recognized by the common people before they were described by the medical profession; that was true of rubella, chicken-pox, and scarlet fever. He thought variola minor was a very good name, and there could be no question that there had been for many years a form of variola which was quite different from the old classical form. Mild cases of the classical small-pox were not the same as variola minor. He was not disposed entirely to agree with Dr. Millard that variola major had been banished, and on that account he was not inclined to assent to the abolition of compulsory vaccination. He thought, however, that it need not be pushed too much; it was good to have it as a standby. He added that, so far as he knew, in small-pox there were no such things as carriers, so that from that point of view small-pox was not administratively difficult.

Dr. H. B. DODWELL said that from the point of view of a local authority they were very conscious of the hostility towards compulsion, and on this ground he was in favour of abolition of compulsion. In his own private practice he tried the effect of persuasion with parents, and never had a refusal. He thought it might be necessary for some compulsory powers to be retained by the local authority in the event of an outbreak of serious small-pox, but, short of that, the method should be by persuasion.

The PRESIDENT drew attention to the oil-painting in the society's room, which showed a group of early members of the society, including Jenner, Lettsom, and Woodville, the men who did most—except Pearson, who was not represented—to introduce vaccination for small-pox into this country 136 years ago. It would be interesting to hear what they would say about the discussion that evening. Had the work of those men been the cause of the very satisfactory position in regard to small-pox, or would the result have been the same supposing their work had not been done?

Dr. KILLICK MILLARD, in answer to another question by the president as to whether there would be a sufficiency of lymph to meet a sudden serious outbreak, supposing compulsory measures were abolished, said that he believed that the Government kept a large store of lymph. (Sir GEORGE BUCHANAN said that the Government had about two or three years' supply in cold

storage.) Taking up the point about the two varieties of small-pox, Dr. Millard declared that it was nonsense to talk about a modified small-pox. Variola minor was a definite entity. They did not know that it was modified; for all they knew, variola minor was just as ancient a disease as variola major. There was no sense in saying that it was modified in the sense that small-pox was modified by vaccination. He spoke warmly on this subject because he believed that there was an ulterior motive behind the resistance to allowing variola minor to be recognized as a separate entity. While he agreed with Dr. Goodall that there were no carriers in small-pox, there was something like a carrier in the unrecognized case of a person who had at some time in his life been vaccinated and who was suffering from a mild attack.

CORRESPONDENCE

The Nutrition Report

SIR,—In view of the political use which has been made of the Association's Nutrition Committee's excellent report (*Supplement*, November 25th, 1933), and for other more practical reasons, it is unfortunate that the terms of reference were not more specific. It is common knowledge that the amount and nutritive value of food required by people following different occupations vary considerably, and even those of the same individual under varying conditions as regards muscular exertion likewise vary. It was therefore a problem to decide whose "working capacity" had to be maintained. The committee widely envisaged that mythical person—the average man doing moderate manual labour. In the case of his family the problem was not so difficult, the requirements of a housewife doing her own work and of school children being more constant.

If the terms of the reference had been more restricted the conclusions of the committee would have been less open to criticism and misinterpretation. As an instance of the latter, Mr. Arthur Greenwood (see *British Medical Journal*, December 9th, 1933, p. 1098) quoted in the House of Commons the diet No. 16 to prove that families on the dole were not receiving adequate allowances. Mr. Greenwood considered the cash outlay on food laid down by the committee as essential for maintaining the health and working capacity of the members of the family; but he disregarded the fact that the majority of families do not come within the definition of diet No. 16, and that the father, being unemployed and on the dole, did not require the full diet of 3,000+400 calories, though the rest of the family would probably require their various quotas in full.

One gathers from Hutchison and Mottram's *Food and the Principles of Dietetics*, seventh edition, Chapter III, that an idle man requires only about two-thirds of the calories he would need when employed at moderate manual work. Thus a saving in the cost of his diet would be achieved. There would seem to be no necessity for an idle man (unemployed for perhaps months on end) to keep up his capacity for work by his diet. Given health, he can easily increase his intake when work is found. On this point the committee would appear to differ from Hutchison and Mottram's textbook. The former, in a note to diet No. 2, states that in the case of the unemployed cutting down this diet would "seriously depreciate its physiological value." That is quite true; but the idle man (according to Hutchison and Mottram) does not require the value prescribed therein. The above considerations should be impressed upon all those who take an interest in the dietetic requirements of the unemployed individual leading an indolent life.

Another point to be noted is that the committee considers that the 39 grams of first-class protein (out of a

total of 100), hitherto thought sufficient, is too low a quantity, and bases its calculations on 50 grams per day, which make the diet correspondingly costly. Diet No. 2 is most varied, and is founded on what the committee discovered as being in use in well-to-do English working-class houses. One most sincerely congratulates the English working classes on the variety and quality and quantity of their diet, and it is to be hoped that they duly appreciate their good fortune as compared with the vast majority of mankind. Even north of the Tweed the English have long been regarded as doing themselves uncommonly well. It may be, therefore, that the committee is quite right in holding that the monotony of diet No. 1 would soon cause distaste and gastric revolt. Sympathy is due to Mr. Greenwood in his anxiety, even though he is somewhat mistaken, about the exact smallness of the sum left over from the dole, when out of such a meagre balance the householder has to provide for such items as rent, coal, clothing, beer, tobacco, artificial silk stockings, dances, cinemas, and football matches—all regarded as so essential to a decent standard of living.

You, Mr. Editor, in an annotation mourn the flippancy of the lay Press in its reception of this most important report; but please take some consolation from the fact that these people regard everything from its news-value aspect, and that even such scurvy treatment is much better than being entirely ignored. It might now be of some advantage to the public if the committee were to take sample individuals at random from various occupations and from the idle, and make an investigation into their general health and capacity for work (if employed) and state of nutrition; ascertain and analyse their usual daily diet, and decide whether such diet is correct in every way for the conditions of existence of each individual. Then draw up a statement (avoiding figures as far as possible) of these investigations, showing where each individual diet exceeds, or falls short of, the person's requirements, or meets the case. Such a document issued to the lay Press for general information might prove valuable, as it would approach the subject more from the point of view of everyday life and practice.—I am, etc.,

Southern Rhodesia, Jan. 12th.

D. CAMPBELL WATT.

Dosage of Barbiturates

SIR,—A few days ago I read a report of an inquest on a victim of dial. During the inquest several medical witnesses gave evidence and were questioned by the coroner on the toxicity of various barbiturates, including dial. One—according to the daily paper's report—replied that the fatal dose of barbitone (veronal) is about 50 grains, and that the same holds good for dial.

I hope this is the inaccuracy of a reporter, and not the actual statement of the medical man concerned, for it is obvious that it is a misstatement in the above form. Dial—the allyl derivative of barbituric acid—is at the very least twice as toxic as veronal, and in my opinion more than that. The fact that it is sold in tablets of 0.1 gram or $\frac{1}{10}$ grains, against the 5 grains of veronal and sulphonal, shows that the average dose is one-third of that of the two simpler compounds. I have personal experience on this subject, having seen a case of dial poisoning where 20 grains were taken, and the patient's life was saved only by the narrowest margin imaginable, and, indeed, was given up by two consultants. In another case—an adult woman—16 grains were fatal after forty-eight hours.

May I appeal on this occasion to those colleagues who have to prescribe—or dispense—these dangerous drugs, never, never, to prescribe them in tablets and in bulk, but to make an invariable rule, as I do, to prescribe them in

divided powders and in combination with pulv. ipecac. and sacch. lactis, like:

R. Diali gr. jss	or	R. Phenobarb. sod. ... gr. jss
Pulv. ipecac. ... gr. iii		Pulv. ipecac. ... gr. ii
Sacch. lact. ... gr. v		Pulv. glycyrrhiz. ... gr. iv
f. pv., nocte s., si op. sit.		f. pv., nocte s.

This combination will have very salutary effects on anyone taking, say, five of these powders, before the soporific has been absorbed in large quantities. Perhaps one of these powders could be included in the B.P. as pulv. phenobarb. co., in which case it could be easily prescribed in suitable cases. Has the time not yet arrived when these compounds should be included in Part I of the Poisons Act, or some of them even in the Dangerous Drugs Act?—I am, etc.

ERIC A. FREYWIRTH, M.D.

London, W., Feb. 5th.

Sudden Circulatory Failure and Diabetic Coma

SIR,—Although insulin therapy has made possible the recovery of cases of diabetic coma, a number of such patients still continue to die. Death can often be attributed to the effects of a concomitant infection, but there still remains a group in which at necropsy no lesions are found, and one has perforce to admit that such cases must be regarded as deaths from uncomplicated diabetic coma. Patients in this latter group usually appear to die suddenly. The clinical picture suggests sudden circulatory failure, and the striking fact about it is that the majority of the deaths occur after apparent recovery from the coma. We have recently met with three cases of sudden circulatory failure after recovery from diabetic coma: one patient died in the condition, one recovered and died from pneumonia forty-eight hours later, and one recovered completely. All had these points in common: the collapse occurred shortly after the patient was raised from the recumbent to the sitting posture; all had previously received a solution of glucose in normal saline intravenously. In view of the recovery under treatment in two cases and the suggestive similarity of the events preceeding development of the condition, it appeared worth while to draw the attention of your readers to these points, in the hope that sufficient cases may eventually be recorded to permit the formulation of efficient preventive or curative measures.

First Case.—Woman, aged 38. Suggestive history of untreated diabetes for several years. Admitted at 6 p.m., unconscious; sugar, "acetone," diacetic acid, present in large quantities in the urine; cellulitis in the left axilla. Treated with subcutaneous and intravenous glucose-saline and insulin. Ten and a half hours later was sufficiently conscious to drink glucose solution by mouth, but the pulse was reported as weak. At this time the urine contained much less diacetic acid. At 9 a.m. diacetic acid had disappeared from the urine, and by the Rothera reaction only a trace of acetone was detected. At this time there was a slight improvement in the general condition, but the pulse was weak. A few minutes past 9 a.m. she was lifted on to a bed pan, and died ten minutes later. After coming off the bed pan she had been propped up on three pillows and actually died whilst sipping fluid. Unfortunately, consent to a post-mortem examination could not be obtained.

Second Case.—Man, aged 50, a known diabetic taking 5 units of insulin twice a day. Admitted at 6 p.m. on the verge of coma. Urine showed a strongly positive ferric chloride and acetone reaction. On examination had signs at both bases suggesting pneumonia. Pulse good. Treated with intravenous glucose solution and insulin. Became fully conscious in four hours and acetone-free in six hours. Three hours after admission it was possible to give glucose by mouth and all further doses were given in this way. At 10 a.m. next day he suddenly struggled into the sitting position and fell back collapsed. When seen he was pale, with cyanosed lips, the respirations were almost imperceptible, the extremities were cold, he was pulseless at the wrist, but faint heart

sounds could be heard. Death appeared imminent. The patient was laid flat in bed, the foot of the bed was raised on blocks, blankets and hot-water bottles put round him, oxygen administered, and 1/16 grain strychnine given. The man's condition rapidly improved, and one hour later was no worse than might have been expected from the pneumonia. He died from the disease two days later.

Third Case.—Woman, aged 36 years (eight months pregnant). Admitted in coma. The urine gave a strongly positive Benedict, ferric chloride, and Rothera reaction. She was given intravenous glucose solution and insulin, and recovered consciousness in four hours. Five hours after admission only a trace of acetone was found in the urine. An hour later she wished to sit up, and was raised by two nurses into a sitting position. Whilst the pillows were being arranged behind her she suddenly collapsed. Her condition at this time was exactly like that recorded in the previous case, and an experienced physician who saw the patient expected her to die any minute. She was laid flat in bed, oxygen and warmth were given, and she recovered in about three hours.

The first question is, To what extent did the intravenous administration of fluid contribute to the production of collapse? We have seen many cases treated in this way which had no such dramatic sequel, and we would point out that in each of the above cases collapse did not occur during the injection of fluid, but some hours later. It would therefore appear improbable that the collapse can be directly attributed to the previous intravenous injection.

The second question is, Can the collapse be due to the sudden raising of the patient from the recumbent position? The time relation of the movement to the collapse suggests that we are here dealing with a causal factor. One of us was present in the ward when the third case collapsed, and he could not avoid thinking of the similarity between the condition and the sudden circulatory failure which may occur in the course of diphtheria. It is well known that in the latter condition such collapse tends to occur if the patient sits up.

We therefore suggest that in our three cases the change to the sitting posture produced the collapse, and this suggestion is strongly supported by the beneficial effect in the last two cases of a return to the recumbent position. If we are correct in our conclusion, the treatment of the condition is obvious. Prevent its occurrence by keeping all cases of diabetic coma flat in bed until forty-eight hours after recovery of consciousness. If by an accident collapse is produced, treat the patient by putting him flat in bed, raising the bed on blocks, applying warmth, and administering oxygen and strychnine.—We are, etc.,

Factors which Regulate the Uterus

SIR,—I was pleased to read Dr. J. M. Robson's letter in the *Journal* of February 10th (p. 262). I should, nevertheless, like to comment on one or two points.

I repudiate the suggestion that in my letter (January 20th) I "ignored" certain facts, although it is quite true that I deliberately avoided discussion, or even mention, of those facts. They were omitted for two reasons: (1) Doubt had been expressed as to whether oestrin has any effect, direct or indirect, on uterine contractions during pregnancy and parturition. The method by which it acts was not in question, and any reference thereto, besides being irrelevant, would have made the communication unnecessarily lengthy. (2) My views as to the manner in which oestrin affects uterine musculature have

been expressed elsewhere. Now, however, that Dr. Robson has introduced the question, may I take this opportunity of saying that for some time past I have held opinions similar in most respects to those expressed in his letter. Moreover, I am glad to learn that his experimental findings lead him to believe that one of the most important actions of the oestrus-producing hormone is to sensitize the uterus as gestation approaches term: this confirms the view expressed by Professor Blair-Bell, Dr. Datnow, and myself in the paper which gave rise to this correspondence. Although this is perhaps the most important mechanism by which this principle exerts its ultimate effect, it must also enhance uterine contractions by reason of its power to cause an increase in size of the muscle fibres. Again, the very reasonable theory that oestrin stimulates the secretory function of the posterior lobe of the pituitary has not yet been disproved. It is true that the original experiments of Dixon and Marshall on this matter have not been confirmed by all investigators, yet others, using different experimental methods, have arrived at similar conclusions. Therefore, until more evidence is forthcoming, there seems no justification in excluding the probability that infundibulin—the most powerful oxytocic substance formed in the body—is concerned in the mechanism of labour.

Finally, may I state that I am extremely interested in Dr. Robson's suggestion that the uterine contents play a decisive part in determining the behaviour of the uterus during pregnancy and parturition. I am entirely in agreement with this view, and personal experiments, together with reports of others, lead me to believe that the placenta secretes not only the oestrus-producing principle, but also the gonadotropic hormones found in the blood and urine of pregnant women, and that, by way of these substances, it is the most important organ controlling spontaneous contractions, and the response to stimulation, of uterine muscle during the progress and termination of gestation. If this conception is true, the gonadotropic hormones are inhibitory, whereas "oestrin" is motor in action. The latter substance probably exerts its effect in at least the three different ways described above.—I am, etc.,

Liverpool, Feb. 10th.

T. N. A. JEFFCOATE.

"Cheap Anaesthesia"

SIR,—Dr. Stanley Sykes, in your issue of February 3rd (p. 215), voices, I feel sure, the opinion of most anaesthetists in the country, and especially of those general practitioners who, apart from their ordinary work, specialize in the administration of anaesthetics.

The anaesthetist, until quite recently, has been regarded by the surgeon as a necessary evil in the operating theatre. Surgeons, as a whole, do not appreciate the skill and concentration that is necessary to make a good anaesthetist. The anaesthetist must be a good physician; he must be able to appreciate the risks attendant upon the proposed operation; and he must choose what is, in his opinion, the best anaesthetic for such an operation before the patient is wheeled into the anaesthetic room. Few surgeons are willing to discuss with the anaesthetist, the day before operation, the suitability of such-and-such an anaesthetic for the patient, or to share with the anaesthetist the difficulties which may be presented to him.

For instance, the use of gas and oxygen may be ideal for a certain abdominal case, and the surgeon may agree; but he must not afterwards be annoyed if he finds that he does not get the abdominal relaxation that is present under ether or chloroform-ether mixtures. Gas-oxygen anaesthesia is by no means easy to administer properly, and the difficulties experienced by the anaesthetist are in no way minimized if the surgeon is continually fussing

and complaining. After a stormy operation the anaesthetist's attitude may well be "anything for peace," and the next time the old-fashioned method is used the surgeon is pleased and the patient has grave post-operative complications and dies. This may well be an exaggeration, but it serves as an example of what may happen if there is lacking a spirit of co-operation between surgeon and anaesthetist.

Dr. Sykes, quite correctly, mentions the cheapness of anaesthesia. A general practitioner, specializing in anaesthetics, may look upon £3 3s., in ordinary circumstances, as the maximum fee obtainable. The public will pay that amount, either to good or to bad anaesthetists, for it does not seem, as yet, to appreciate the services of a skilled anaesthetist, meticulous though it be as regards a surgeon. The cost of gas and oxygen to an anaesthetist for an operation lasting one hour is about 17s. 6d., a third, nearly, of the fee, which remains the same whatever anaesthetic may be used. It seems only reasonable, therefore, that the public should be denied the benefits of modern anaesthesia until it appreciates the cost of apparatus and running expenses, and until it pays the anaesthetist the fee to which he is entitled. For be it from me to suggest that surgeons are overpaid, but I do definitely think that anaesthetists in general practice are underpaid.

In conclusion, has not the time come for a diploma in anaesthetics to be given to those who, desirous of being specialists in the subject, can satisfy a board of examiners that they possess a knowledge above the average?—I am, etc.,

GRAEME BENTLEY, M.D. Cantab.,
— Anaesthetist, Jersey Dispensary.

Jersey, Feb. 4th.

Gas and Oxygen Anaesthesia

SIR,—The article on the history and development of nitrous oxide by Mr. H. Edmund G. Boyle is most interesting and timely as a reminder to the medical profession of the opposition that there has always been from the profession itself to anaesthesia and advances in the same. We are all, especially the women of England, indebted to Mr. Boyle for his persistent advocacy of nitrous oxide and oxygen for confinement cases and all gynaecological things, even though he does very often give a little ether with it.

I am pleased to see that he mentions E. I. McKesson of Toledo very favourably, but he says that McKesson's method of giving gas is rather alarming. I saw him do it and did not find it so, and, moreover, the condition of McKesson's patients was always better than those to whom ether had been given in however small an amount. The secondary saturation of McKesson is the reply to those doctors who say that relaxation cannot be got with nitrous oxide and oxygen. McKesson gets it. I have seen him do it for gall-bladder cases, stomach operations, and every abdominal operation that can be mentioned also. The question of relaxation is only a matter of how far you are prepared to go. For most cases it is not necessary to go to the length that McKesson does, and, although it is safe, so far as I have seen, with McKesson, I am in agreement with Mr. Boyle that it is not a method to teach students; but I would add this proviso—that it is a method that should be taught to any man who is taking up anaesthesia as a specialty.

The real reason why gas and oxygen is not more used is (as I have heard it expressed many times) that it is not a business proposition for the practitioner. The apparatus is expensive, and it requires a fair amount of skill and attention to use it. Therefore patients have to put up with open ether and even chloroform for such small things as teeth extraction.—I am, etc.,

Doncaster, Jan. 31st.

E. J. CHAMBERS.

A Falling Birth Rate

SIR,—The interesting letter on the above subject in your issue of February 3rd (p. 219) by Dr. Harry Campbell is one which calls for more than passing comment. He paints the picture black enough, and I may add true enough; but one may ask, What vantageth it to increase the population without a due regard to a selective birth rate? We have got a selective death rate, which is useless so far as the quality of the population is concerned unless we look after its forerunner—a selective birth rate. In 1918 Mr. Lloyd George declared that "the result of the physical examination of the manhood of Great Britain demonstrates that the physical condition of the British people is lower than that of any other civilized country." Since then matters have been allowed to drift, though there is no reason to think that the general physical condition has in any respect improved.

The medical profession as a rule leave the birth rate alone, and, like other classes, have long since ceased to add many to the population; they are quite content to point out the fall in the death rate, and complacently tell you that the average length of life is increasing, forgetting that this increase is almost entirely due to the fall in the birth rate. A man owes his health and longevity largely to his progenitors, near and remote, so the medical profession often get more credit than is their due. If we only stopped the reproduction of the unfit, the fit would then be able to look after themselves, and the selective evolution of the race would go on rapidly. It is not now a question of the survival of the fittest; your industrious, independent, hard-working man who is taxed to support the loafer, the wastrel, the pauper, the criminal and the progeny of the degenerate, does not live to eke out an existence with an old age pension. It is your miserable degenerate, who is assisted by charity from the cradle to the grave, that often survives the longest. Some time ago I was called upon at a prisoners' aid society in Liverpool to propose a vote of thanks to the two judges of Assize. *Inter alia* I said that Mr. Justice Bailhache deplored having to pass a long term of imprisonment on a man aged 70 who had already spent fifty years of his life in prison. I suggested that a life of crime is not necessarily a short one, and if this individual had been a hard-working honest man he probably would have been dead long ago. Too much sympathy may be easily wasted on individuals of this type, and perhaps permanent detention is the simplest way of dealing with them. Nature, when free to act, weeds out the unfit, but on account of our benevolence and charitable sentimentality the mental and physical weakling has often in the present day a better chance of survival than the strong and fit. The degenerates not only survive, but they are more prolific than the intellectual; they are not hampered by any economic laws, and they rapidly produce another generation more degenerate than themselves. Nature's method of adapting the individual to the environment, which is the surest method of progress, has been reversed, and we now adapt the environment to the individual—temper the wind to the shorn lamb.

In the eighteenth century, "the age of enlightenment," we had a high birth rate and a high death rate with a small but very intellectual population, who did their fair share in acquiring and populating fresh lands. We want a race of choice, not of chance. The derelicts are of no use either in peace or war, but what to do with the enormous number which we have on hand is the puzzle. No country on God's earth, not even our own colonies, will relieve us of this burthen. This would be a good job for Mr. Lloyd George and Dr. Harry Campbell in their spare time.—I am, etc.,

JAMES BARR.

Hindhead, Feb. 7th.

Eugenics and Sterilization

SIR,—Lord Horder, in the *Journal* of December 9th, 1933 (p. 1057), sets out to discuss: (1) what is meant by eugenics, (2) the attitude of the public towards eugenics, and (3) the position of the doctor in relation to eugenics. He accepts Galton's definition of the term, which, he says, "includes two main influences . . . the influence of environment . . . and the influence of heredity." Then, to our surprise, he dismisses in a few words the influence of environment and devotes the remainder of his address to the influence of heredity.

It soon becomes plain that to Lord Horder and the Eugenics Society eugenics means the study of the influence of heredity only, and the main application of eugenics consists in the sterilization of the unfit. Anyone opposed to the operation of sterilization of the unfit is an opponent of eugenics. Those who do not support the sterilization of the unfit are soon grouped by him into two classes: (1) those who "from a fundamental inability to think clearly" remain indifferent; (2) those who have "got the question of racial improvement mixed up with religion." The entanglement causes them to oppose "active measures of a eugenic kind," the chief of which, of course, is sterilization of the unfit.

The source of this opposition is dismissed in a few words. Apparently it arises from two superstitions: (1) "the primitive association of procreation with magic, and, later, with divine influence"; (2) the fact that the mentally deficient were by many races deemed to be possessed of some special sign of grace. Having thus disposed of all opposition, Lord Horder goes on to make an eloquent plea for the more intensive study of eugenics, a plea which will gain the support of every one of his professional colleagues.

But I suspect that Lord Horder's contemptuous dismissal of all objections to his proposals arose more from impatience than from reason. Sir Henry Brackenbury, at the Centenary Meeting of the B.M.A., adduced some telling arguments against sterilization which could not have been derived from either of the two superstitions mentioned by Lord Horder. The writings of theologians, too, must have met with but scant perusal at the hands of Lord Horder, for otherwise he would certainly be aware that their objections arose from sources much more fundamental, and that their reasoning follows a logical train of thought.

No branch of Christianity is opposed to eugenics as originally defined by Galton. On the other hand, it is its most enthusiastic supporter. Religion has always been in favour of sufficient nourishment, fresh air and exercise for growing children, decent housing conditions, temperance in the use of alcohol, more skilful obstetrics, segregation of the insane and mentally defective, the eradication of syphilis and other communicable diseases. It also advises against the marriage of people who are likely to transmit any defects to their offspring. But the Eugenics Society does not appear to include those pressing social needs in its programme. Can anyone doubt that the overcrowding and the undernourishment of England's large cities are a fertile cause of the increase in inefficiency; that there is more than chance in the association of the rise of industrialism with the alarming increase in the proportion of mental defectives in England? As to sterilization itself, nobody can pretend that it would cause any appreciable reduction in this proportion. Less than 5 per cent. of defectives are the offspring of deficient parents; wholesale sterilization, therefore, would decrease mental deficiency in the next generation by less than 5 per cent. Against this small decrease we have to balance the evils of the setting free of many defectives at present segregated.—I am, etc.,

MICHAEL KELLY, M.B., B.S.
Banbury, Western Australia, Jan. 11th.

Voluntary Sterilization

SIR,—In 1925 the suggestion was made at the Medico-Legal Society by a leading member that, notwithstanding a client's request, a surgeon who did a sterilization on other than serious therapeutic grounds might be liable to a criminal prosecution under the ancient law of maiming. Because of this suggestion the operation has ever since been almost universally regarded in England as being legally like artificial abortion! An *ad hoc* departmental committee has now advised that voluntary sterilization be legalized for certain defectives and for probable carriers of grave transmissible defect. I deplore that its report recommends that the operation be not made available to normal persons. It should, on eugenic and other grounds, be made available to any person with two children who desires it.—I am, etc.,

London, S.W.7, Jan. 27th.

B. DUNLOP.

Hereditary Blindness

SIR,—It would be impossible, in the interests of our blind population, to overlook Mr. Cecil Tivy's statements in the *British Medical Journal* of February 3rd with regard to my paper, "The Menace of Hereditary Blindness." I will answer all the points he raises.

In no place in my paper do I state that there is an annual increase in blindness, although this is by no means improbable, owing to dysgenic selection and the increasing expectation of the years of life; this latter factor also makes the birth of a blind child so much the more serious owing to the possibility of, say, a hundred years of blind life. I stated clearly that it was only the registered blind that showed increases.

Having collected figures over six years, I have found that at my clinics, for every blind person registered I have seen four that were not, and many of these were never likely to be registered as matters stand to-day. That is where the 250,000 figure comes from. With a register of 70,000 the figure would be 350,000. I prefer to make the understatement. I have certainly not overlooked categories 3, 4, and 5—that is:

3. Those who become blind after leaving school at 14 or later, and are not registered until reaching blind pension age at 50. Many of these refuse to be certified, regarding it as rather a disgrace.

4. Those who become blind after 68 and are not registered. They obtain the old-age pension, which is the same in amount as the blind pension—namely, 10s. weekly. This is a very large group, and is likely to grow as the average length of life increases.

5. Those blind persons who are eligible for the blind pension—that is, they are between the ages of 50 and 65—but who do not apply for it because they have never heard about it.

I have seen very large numbers of unregistered blind in these groups.

Mr. Tivy asks how 1 in 15 senile cataracts can be prevented. I did not state that 1 in 15 could be prevented. I did, however, include 6 to 7 per cent. of senile cataracts as possibly hereditary; reference to Nettleship Memorial volumes of the *Treasury of Human Inheritance* and other authorities will show large numbers of pedigrees where it would appear to be so. This 6 per cent. of senile cataracts was included in the list of largely avoidable groups of blindness, and if Mr. Tivy will read a simple book of genetics, say, Lindsey's *Textbook of Genetics*, he will learn how inherited defects can be avoided.

He would like to know "how all cases of blindness due to myopia can be prevented"! As I made no such claim whatever, and explained the present knowledge with regard to the hereditary nature of myopia at length, such a question coming from an ophthalmologist proves that

my paper has had a superficial examination. Mr. Tivy probably forgets that environment also plays a definite part in the avoidance of blind myopics.

Here Mr. Tivy "skips on" a long way to the last column, to my "possible remedies": (1) constructive birth control to avoid overcrowding and poverty; and (7) the Wassermann reaction during or before pregnancy, which he says "are the only sensible suggestions, and those not even mainly for their influence on hereditary blindness." Mr. Tivy here proves that he is not aware of the fact that "constructive birth control" requires a knowledge of the chief hereditary factors and simple biological principles, and is therefore of paramount importance to the reduction of hereditary blindness. The Wassermann reaction used in the way I suggested is of extreme value in avoiding congenital syphilis and the interstitial keratitis cases, known as a pseudo-heredity, and it is of sufficient importance to be mentioned in a paper such as mine.

If Mr. Tivy will refer to my article in the *British Medical Journal* of April 30th, 1932, "The Welfare of the Blind and National Economy," he will understand how I have the cause of the prevention of blindness at heart. Does he realize that large numbers of blind persons have been placed on the blind register since the war without examination by eye specialists, and that many doctors have signed these certificates without knowing the standards of blindness thoroughly, and also without payment at all in many cases, and without adequate payment in large numbers of cases; that some have been registered by persons other than doctors; and all this in spite of the recommendation of the B.M.A. that £1 ls. per case should be paid for this important work? An examination in the busy out-patient department of a voluntary or other hospital without payment will never lead to the satisfactory registration of causation, heredity, treatment or operation, training possibilities, etc.; and only experienced eye specialists can do the work properly, and then only with the necessary time.

The certification of the blind is nobody's business. The blind person cannot be responsible, for obvious reasons, and he often objects to certification; the surgeons at the clinics are often loath to mention the subject, in the rare event of their thinking about it or knowing the necessary standards and procedure. There are a large number of borderline cases for examination, and these are often the most difficult to decide upon.

Ophthalmologists must not forget that, in addition to the sight-testing opticians, unqualified eye practice is still permitted in this country; and I doubt if it would be tolerated were a full blind register in existence. Are people aware that more and more careers are being closed to individuals who are born with, or develop, comparatively small defects of sight (myopia, astigmatism, colour-blindness, etc.)?

Only last Thursday I saw four blind persons who were not on the register, nor ever likely to be; one woman stated quite simply that her husband would not like her to accept charity, and she herself would much prefer not to be on a blind register. In two of the cases it was highly undesirable to mention the subject, as both the patients hoped for improvement (which was unlikely in their cases). I am especially anxious that a full and accurate blind register may be obtained (unilateral blindness is important), and then we shall know still more about the balance between heredity and environment, and prevention will be facilitated. The time has come to respect the rights of the unborn child; my recommendations are preventive in character, and readers can easily judge as to their degree of efficacy or desirability.—I am, etc.,

J. MYLES BICKERTON,
Senior Ophthalmic Surgeon, King's
College Hospital.

London, W.1, Feb. 5th.

Painful Injections

SIR,—Dr. Bousfield's letters have been both timely and practical, but I should much like to know whether his objection to the possibility of aspirating spores into a syringe from the air has any basis in fact. While not denying the possibility, I am sure that it would interest many of us to know whether any harm has ever resulted from it occurring. How much does the customary dab of spirit do to prevent sepsis (personally I always use iodine), and how many cases of trouble arose from the innumerable hypodermic injections given during the war through completely unsterilized skin? While not advocating any departure from aseptic principles, I believe that many of us, as scientific men, would like an answer to these questions. Furthermore, while always using sterilized water if available, I have never had any trouble from washing out my syringe with cold water running straight from the tap. Is the local water supply peculiarly sterile, or is the body well able to deal with an occasional bacillus introduced under the skin with the minimum of trauma?

There is one practical point about injections which has not so far been mentioned. Some people, usually, I think, of the fat type whose skin puckers on being pinched, have a peculiar kind of subcutaneous tissue in that, if pricked, the track of the needle remains patent for a short while. As a result, solution injected a good inch under the surface will often exude after the needle is withdrawn. Haemorrhage in these people may come from a deeper layer than could be detected from examination of the avascular areas. They seem more liable than most to get "bad arms." Such cases may, I believe, be due to bacteria being rubbed by the patient into the still patent orifice made by the needle. Since I have made a practice, in this type of patient, of keeping up digital pressure for a minute or so after the needle is withdrawn I have had much greater freedom from bleeding or regurgitation of fluid and no inflammatory reactions.

I would also like to draw attention to the valuable suggestion of keeping a little air in the syringe when injecting any painful solution intramuscularly. If this bubble of air is injected after the solution it cleans out the needle and helps to prevent a painful track forming in the subcutaneous tissue.—I am, etc.,

Winsford, Cheshire, Feb. 5th.

W. N. LEAK, M.D.

Pruritus Ani

SIR,—I find that my letter in the *Journal* of January 20th (p. 123) has elicited two replies—one corroborative, the other critical. Mr. A. S. Mouley (February 3rd, p. 216) accuses me of "the common error of writing on pruritus ani as if it were a disease *sui generis*, and of referring to it as being 'curable' by x rays." Well, in its idiopathic form, which is very common, it is as much a disease entity as many other symptom-complexes whose title is not disputed; and if to be freed for several years by a single course is not a "cure," at least most patients are content to call it so.

It is true that the radiotherapist sees a much higher proportion of idiopathic cases than obtains in general practice. In view of the care and skill exercised by the modern general practitioner, this is inevitable. The causes enumerated by Mr. Morley are well known to the family doctor—more particularly the role of parasites. The average case which is sent to the consulting radiologist has been carefully investigated, and there are thus *a priori* grounds for believing it to be of idiopathic type. As x-ray treatment is convenient, clean, and quick in its results, there is no reason for not trying it. Failure or

quick relapse is in itself of diagnostic value, as it indicates that there is some cause which will probably be discovered by more intensive search—or that the condition is, in the particular patient, of neurotic origin.

There are two other points in Mr. Morley's letter which I should like to touch upon briefly. He mentions "anaesthetic remedies or x rays" in conjunction, as though there were some similarity between them. Now I understand that Mr. Morley is an authority on anaesthesia, but obviously he is not a safe guide as to x-ray action. Those of us who have studied it most know little about it, but it is at least certain that x rays in suitable doses stimulate the skin and underlying tissues to resist microbial invasion. This is evident in the treatment of acne, and no one who has seen the dramatic drop of temperature in acute erysipelas after one or at most two x-ray applications could possibly doubt it. Then there is the matter of operation for haemorrhoids. I assure Mr. Morley that I had no thought of taking part in a controversy between surgeons who "operate" and those who "inject." I used the word "operation" to cover any mechanical procedure for the destruction of piles.—I am, etc.,

London, W.1, Feb. 6th.

F. HERNAMAN-JOHNSON.

X-Ray Cinematography

SIR,—You were kind enough to insert a notice in your issue of December 25th, 1926, with reference to a paper I was reading before the Röntgen Society on January 11th, 1927, on my work in connexion with x-ray cinematography. This work was initiated by me in 1921, and a thesis submitted to the University of Cambridge in 1925. Subsequently to the paper read before the Röntgen Society, I read a paper before the American Röntgen Ray Society, and showed some films of a thorax, etc., in September, 1927. The account of this was published in the *American Journal of Roentgenology* in May, 1928. During the latter end of the past year I have succeeded in bringing the subject to a really practical issue, and have been able to obtain x-ray cinematograph films of all the moving parts of the human body; more especially I would mention the movements of the stomach and intestines after the administration of a barium meal.

It is thus possible to study abnormalities in the alimentary tract. Movements of the heart and thorax were obtained some years ago; I was able to show these in 1925.—I am, etc.,

RUSSELL J. REYNOLDS, C.B.E.,

Treatment of Early Breast Cancer by X Rays

SIR,—The discussion upon radiotherapy at the recent Radiological Congress, together with the views expressed in your columns from time to time, make clear the lack of co-ordination and co-operation between English radiotherapists. This, I think, is to be deplored, since it precludes any possibility of progress in this important branch of modern medicine. If a correct evaluation of deep therapy is to be achieved, it can only be done by careful comparison of results between practitioners employing exactly similar methods. I am therefore tempted to suggest a definite line of treatment in early breast cases, in the hope that some colleague will adopt the method and make it possible to compare results at some future date.

I specify *early* cases (and naturally infer those showing no obvious extension to glands or elsewhere), since they alone will prove or disprove the efficacy of the method. Nevertheless, there seems to me no valid reason why it should not be employed even in advanced cases. Our main problem in these, as indeed in all malignant cases,

is the question of metastases, and to my mind their prevention (if possible) should be our primary objective rather than the original tumour. Unfortunately other sites are not so accessible as the breast, but I maintain it should be attempted whatever the location. Here let me state that I claim no originality for the method; it was introduced to me (in modified form) by Professor J. Woodburn Morison.

He adopted it in cases with surrounding skin metastases, and with excellent results. Furthermore, post-mortem observation of patients under treatment and who died of metastases or intercurrent infection revealed definite areas of necrosis within the tumour where heavy dosage had been given, together with varying degrees of hyperplasia or thickening of the surrounding connective tissue. These changes were not apparent where fractional dosage was the method of choice or when soft radiation had been employed. It is therefore logical to assume that we can constrict or impair the circulation in surrounding blood vessels and lymphatics, and thereby hinder the passage of active cancer cells. One case in particular impressed this fact upon me, and led me to believe that herein lay a rational line of attack. I will refer to it later. The method of procedure is as follows:

The optimum voltage, in my experience, is in the neighbourhood of 180 kV with 0.5 mm. Cu-filtration. The preliminary treatment consists of an attempt to seal off the primary growth, and to this end an erythema dose is given to the outlying quadrants, carefully avoiding the lesion itself. The apertures used are sufficiently large to form a closed square, and the f.s.d. is 40 cm. The axilla and supraclavicular areas are next treated, but a dosage of 450 r is, I think, sufficient for these, provided the former have been adequately dealt with. Then an interval of three or four weeks is given; this I think essential to allow for deep tissue reaction. Meanwhile, the untreated primary will often be found to have diminished in size. Finally, the breast itself is irradiated by combination of direct and glancing methods, in order to ensure complete irradiation of the entire neoplasm.

The case referred to above was treated on these lines, except that the inner quadrant was overlooked. An otherwise excellent result was marred a few months later by a recurrence in the opposite axilla, though the breast on that side was perfectly healthy.

I firmly believe that this method will prove of value in all cases. It is well tolerated, and I have yet to see any suggestion of damage to the thoracic contents.

On these principles there should be a wide field as yet unexplored for deep therapy, and, as I see it, a chance of fuller justification. Radium and x rays are double-edged tools, capable of retarding the spread of malignant disease when used rationally, but also capable of accelerating the spread when used indiscriminately. Radium I regard essentially as a weapon of offence; x rays, when used conjointly, a weapon of defence. But I maintain that defence must precede offence. Those of us who have treated pelvic extensions in cervix cases subsequent to radium application realize the futility of this following-up irradiation. In upwards of 100 cases I saw not a single response. Once extension has occurred no treatment can avail. Surely, then, the rational course would be x-ray treatment: first a short interval, then the application of radium.

Most primary tumours are in varying degree radio-sensitive, but the same cannot be said of secondary growths. If, therefore, we have a means of preventing the latter, then let us use it; but at the right time—that is, before the active malignant cells have time to escape, in company with the necrosed products of intensive radiation. Here, as I see it, lies a future for deep therapy, and herein lies a fruitful field for research.

Since this note was submitted for publication, Dr. Gilbert Scott has advocated somewhat similar principles in this *Journal*, together with x-ray baths. The latter

method is certainly deserving of more attention, and general radiation at low milliamperage should be tried, but always prior to surgical or other treatment. It seems to me that with treatment metastases change in type, tending to reproduce the original tumour in the form of massive deposits in the lungs, vertebrae, etc. Whereas, formerly, in long-neglected breast cases one frequently saw generalized dissemination of the miliary type, such types to-day are rare, at least in my experience. In any case, it does seem more rational to employ x rays when they might be of service rather than to fall back upon deep therapy only when nothing short of the miraculous could be effective.

In conclusion, I would urge the British Institute of Radiology to draw up definite standards of routine treatment with a view to their general adoption. Only by co-operation can progress be achieved, and radiotherapists would do well to follow the example of their radium confreres by forming a branch society.—I am, etc.,

Colwyn Bay, Feb. 4th. W. GRIFFITHS, M.B., D.M.R.E.

The Tuberculosis Problem

SIR,—I rejoice to see the letter by "A. R. F." in the *Journal* of February 3rd, as its subject is one I have so often, with no avail, written about for years. If we returned to the well-thought-out policy of the Astor Commission, and adhered to it, we would as a profession again get the confidence of the public, who are now better versed than in 1912 in what tuberculosis means, while the thousands of consumptives who have been to the various sanatoria have educated many more thousands of their relations about the open air and the more modern treatment received there. The use of x rays is universal in sanatoria, and the public know quite well nowadays that no diagnosis is complete without a film. Yet very many tuberculosis dispensaries have no x-ray apparatus, and when up-to-date general practitioners bring films along many so-called specialists cannot even read them. The result is that the tuberculosis patient has no faith in his outside specialist, but returns and asks the medical superintendent to examine him. This obviously cannot be done. The general practitioner simply uses this "omnibus expert" as a clearing clerk to get the patient into a sanatorium where the medical superintendent treats his patient properly.

That there are far too few beds in most counties and cities is a crying shame, but finance lies at the bottom of an economic policy which is unsound from the standpoint both of treatment and of prophylaxis. The pioneer work of King Edward VII and Mr. Lloyd George is being stultified. To neither of these two has sufficient credit been given in the past. I feel sure that when trade returns the "intermediate T.B. interlopers" will give place to the properly trained men of 1912. The fully trained chief tuberculosis consultants are never used properly, human nature being what it is. I feel certain that all my fellow specialists will agree with everything I have written.—I am, etc.,

February 4th.

JAMES D. MACFIE.

SIR,—The extremely pessimistic letter of "A. R. F." in the *Journal* of February 3rd must have come as a shock to tuberculosis workers. No, Sir, there is not much wrong with our anti-tuberculosis campaign *provided that it is efficiently carried out*. I do not think there can be many areas in this country such as the one described by "A. R. F." but I do know that the Ministry of Health inspectors are constantly employed in gingering up local authorities who are so niggardly in their expenditure that the anti-tuberculosis measures in their districts are extremely inefficient. Tuberculosis

dispensaries should not only be provided with highly qualified and well-paid officers, but also equipped with efficient x-ray departments and all other aids to modern methods of diagnosis. In the areas with which I am familiar in the North of England no expense is spared by the local authorities to bring this about, and they are of real assistance and enjoy the complete confidence of the local practitioners; as well as the staffs of the local hospitals.

"A. R. F." asks whose fault it is that cases are not recognized or sent for treatment until in an advanced condition. A long experience as senior medical officer in a tuberculosis dispensary has shown me that this, in a majority of cases, is due to the patients themselves not seeking the advice of their medical man at a sufficiently early stage, although I must admit that some cases are due to the perfunctory examination of the patients whilst attending their medical practitioner. In my annual report of three years ago concerning the work done in this department the following note appears:

"It is a remarkable fact that many cases of pulmonary tuberculosis reach a comparatively advanced stage before the patient seeks the advice of a medical practitioner. It is worthy of note that in many reports from the patient's doctor accompanying such advanced cases to the dispensary occur the words, 'I have only seen this patient for the first time a few days ago.' It is astonishing that pulmonary tuberculosis can reach such widespread distribution in the lungs without producing symptoms sufficiently striking to cause the person affected to seek advice, and it is often difficult to make patients and their friends realize that serious disease is present in the chest."

I find that the younger practitioners are more alert in the search for pulmonary tuberculosis than the older men, because they have had better tuition during their university career. In my own area, which is in a northern city, I endeavour by means of post-graduate lectures to bring to the notice of local medical men suggestions for the better diagnosis of pulmonary tuberculosis. I have suggested that it is necessary to impress on G.P.'s the following points:

1. That all persons who have suffered with a cough which has not responded to treatment spread over four or five weeks should have the sputum examined, and also be referred to the dispensary for examination.
2. That all cases of primary pleurisy, especially those with effusion, are almost certainly tuberculous, and should be referred for examination with a view to sanatorium treatment.
3. That persons of old age who suffer with a chronic cough are in many cases tuberculous, and are the source of infection to younger persons living in the same house.

As Dr. Ernest Ward admirably says in a recent paper:

"The general practitioner occupies the front line in our fight against tuberculosis, and he could aid tuberculosis officers in discovering sources of infection if he made a habit of considering the families of his tuberculous patients, speculating whence came the infection, and persuading likely sources to be examined and radiographed."

I am most gratified to state that in my own area the liaison between the dispensary medical staff and local medical men is admirable, and we do our utmost to give them all the help we can. We have a completely up-to-date x-ray equipment, and every new case sent to the dispensary has a radiogram taken of the chest, and in cases where lesions are found a photographic copy of the radiogram is forwarded to the practitioner concerned, along with a complete report of the condition discovered. That this is helpful is shown by the number of letters of appreciation which I receive. I feel sure that similar methods are used in all efficient dispensary areas. It is gratifying to note that in this city deaths from pulmonary tuberculosis have been reduced by 50 per cent. during the last twenty to twenty-five years, and during the past twelve months we have been unable to keep our sanatorium beds filled owing to the lack of new cases of tuberculosis.

I trust that the information given above will reassure "A. R. F." that anti-tuberculosis measures are being efficiently carried out in at any rate many parts of this country.—I am, etc.,

E. N. R.,
February 8th.
Senior Tuberculosis Officer.

Rest in the Treatment of Neuroses

SIR,—My letter in the *Journal* of December 30th, 1933 (p. 1231), was not written for the instruction of such an authority on the neuroses as Dr. Macdonald Ladell, (January 27th, p. 174), who needs no such hints as I ventured to give, but rather for the harassed general practitioner who has not had Dr. Ladell's opportunities of appreciating the exhausting mental and physical effects of mental conflict. I called attention to the causes of the exhaustion, which I considered should be mitigated by rest rather than increased by what I regarded as unprofitable waste of energy. I did not for a moment intend to convey the impression that rest in bed under mild sedation in these cases should in any way replace or render unnecessary every possible endeavour of the physician to help the patient to unburden himself of the causes of his conflict, with its consequent anxieties and exhaustion. I perhaps did not stress this so much as I might have done, because my object at the time was rather to point out the need for recognizing that patients such as I had in mind are already exhausted and, till relieved of their mental stresses by some adequate form of treatment, are quite unfit to make the further efforts that I find they are too often urged to make. That these efforts only add to their anxieties and feeling of hopelessness can, I think, hardly be denied, since they feel themselves unable to—and, indeed, many of them cannot—make the effort required.

I entirely agree with Dr. Ladell that the necessity and even the wisdom of insistence on such rest as I advocated is a matter for decision in each individual case, and that in any event the reason for such rest and its limitations must be thoroughly understood by both physician and patient. If this is the case I do not think there should be any danger of assisting the patient, merely because he is in bed, to "withdraw himself from his efforts at adaptation"; on the contrary, my object in such practice is to conserve the energy of which he is already short, and which he has been expending fruitlessly, so that he may have as much as possible available for use, when rightly directed, for such a adaptation. Does not whether "the patient finds himself back in the infantile position of irresponsibility which his Unconscious has desired" depend on his physician's treatment of him when in bed rather than on the mere fact of his being in bed, as Dr. Ladell seems to suggest it does?—I am, etc.,

J. W. ASTLEY COOPER.
Middleton St. George, Co. Durham, Feb. 8th.

* This correspondence is now closed.—ED., B.M.J.

Rest and Chorea

SIR,—With regard to the incidence of infantile chorea I shall be most interested to know if others have noted—as I have done—that this disease is almost entirely confined to the artisan classes. Though I have had quite a considerable number of cases under my care in hospital, I cannot recall a single instance among my private patients. I have been trying to fathom a reason for this. It cannot be lack of nutrition, as many of these patients are quite well nourished and come from homes where there is no lack of the necessities of life. I have found, however, that these children often go very far short of the amount

of sleep they should have for their age. I once had an inquiry made as to bedtime hours in all chorea cases admitted to hospital under me. The result quite bore out my expectations—that is, that these children were up hours after they should have been in bed. For example, children of 10 years of age and under were running about till after 9 p.m.

In the treatment of chorea I am quite sure rest is the most vital factor. One has seen quite a variety of drugs used at different times for this complaint, and usually good results are obtained from them all, provided the case is also kept strictly at rest. May it not be also conceivable that the heart condition, so often found associated with chorea, is due, anyhow in part, to the same cause? The heart in this child has been overworked, and has succumbed to an infection that otherwise it might have resisted. Some observers have noted that the heart in children develops irregularly, and that when the period of rapid growth is taking place the softer fibres are more prone to injury and disease.—I am, etc.,

Wolverhampton, Feb. 6th.

E. HAYLING COLEMAN.

Ultra-violet Rays and Seminal Stains

SIR,—In his letter in the *Journal* of January 6th (p. 37) Dr. F. W. Martin very rightly draws attention to the value of filtered ultra-violet light in determining the site of seminal stains; he does not, however, point out that in the present state of our knowledge evidence of fluorescence alone, uncorroborated by chemical or microscopical tests, is insufficient proof that the stains are due to semen and to nothing else. Work on fluorescence is being carried out in this laboratory, but must still be considered to be in the experimental stage, and a considerable amount of work remains to be done. At the present time I advise the use of filtered ultra-violet light for locating a stain which is not obvious to the naked eye, followed by chemical or microscopical tests for determining its nature.—I am, etc.,

NORMAN BURGESS, M.A., M.D., M.R.C.P.

Criminal Investigation Research Laboratory, Central Police Station, Bristol, Feb. 6th.

Universities and Colleges

UNIVERSITY OF OXFORD

Dr. William Stobie, Hon. M.A., has been appointed representative of the University at the conference of the National Association for the Prevention of Tuberculosis.

UNIVERSITY OF CAMBRIDGE

Dr. Eric Holmes has been appointed a member of the Faculty Board of Medicine until December 31st, 1934, in the room of Dr. R. A. Webb. Mr. W. H. Bowen, M.S.Lond., F.R.C.S., has been appointed a member of the M.D. Committee until September 30th, 1934, to fill the vacancy caused by the resignation of Sir F. Gowland Hopkins.

The third report of the Council of the Senate on proposed amendments to the regulations for academical dress is published in the *Cambridge University Reporter* of February 6th. The recommendations end with a proviso that a member of the University may continue to wear any academical dress which when he first wore it conformed to the practice of the time.

At a congregation held on February 10th recommendations for the establishment of a Sheild Readership in Pharmacology in the Faculty of Biology "B" and of a Subdepartment of Pharmacology in the Department of Physiology, were approved. Recommendations in regard to the Molteno Institute of Parasitology were also approved. Professor E. H. Kettle, M.D.Lond., was appointed an elector to the Professorship of Animal Pathology in succession to the late Sir William Hardy. Professor G. H. F. Nuttall was appointed to represent the University at the centenary of the University of Bern, in June next.

The following medical degrees were conferred on February 10th:

M.D.—S. Vatcher.
M.B., B.Chir.—G. F. Barran.
M.B.—C. R. T. Lane, W. D. Brown.
B.Chir.—E. C. Herten-Graven, A. R. Thomas, E. G. Pyne.
A. C. L. Houlton, J. Smart.

The title of the degree of B.Chir. has been conferred by diploma on E. D. Thompson of Girtton College.

The following candidates have been approved at the examination indicated:

DIPLOMA IN MEDICAL RADIOLOGY AND ELECTROLOGY.—(Part I): J. D. P. B. Boyd, A. A. Danlevy, J. H. Gillespie, T. R. Harlan, M. S. Kavarna, A. U. Millar, G. R. Nolan, H. I. Osler, J. P. Raban, C. W. Robertson, T. F. Tierney.

UNIVERSITY OF LONDON

Dr. G. P. Wright has been assigned to the Faculty of Medicine as from March 1st.

Mr. H. L. Eason, C.B., C.M.G., has been reappointed representative of the University on the General Medical Council.

Applications for grants from (1) the Dixon Fund, for assisting scientific investigations, and (2) the Thomas Smythe Hughes and Beaverbrook Medical Research Funds, for assisting original medical research, must be sent in between April 1st and May 15th. Particulars can be obtained from the Academic Registrar.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

A meeting of the Council of the Royal College of Surgeons was held on February 8th, with the President, Sir Holburt Waring, in the chair.

The President reported the appointment of Mr. Victor Bonney as Bradshaw Lecturer for the ensuing collegiate year. Mr. Bonney was also re-elected the representative of the College on the Central Midwives Board.

Diplomas

Diplomas of Membership were granted to the following candidates who have passed the final examination in medicine, surgery, midwifery, and pathology of the Conjoint Board: W. Bullock, H. D. Fairman, J. R. Kingdon; and to 150 other candidates whose names were printed in the report of the meeting of the Royal College of Physicians of London in the *Journal* of February 3rd at page 220; as were the names of the fifteen candidates who have been granted Diplomas in Public Health.

Council Election

The President reported that an election of four Fellows into the Council would take place on Thursday, July 5th next, at 11 a.m., in the vacancies occasioned by the retirement in rotation of Mr. Ernest W. Hey Groves, Mr. G. Grey Turner, and Mr. Hugh Lett, and by the death of Mr. R. P. Rowlands; that notice of the election would be given to the Fellows by advertisement and by circular on March 9th; that March 19th would be the last day for the nomination of candidates; and that a voting paper would be sent on April 3rd to every Fellow of the College whose address was registered at the College.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

A meeting of the Royal College of Surgeons of Edinburgh was held on February 5th, when Dr. A. H. H. Sinclair, president, was in the chair. The following candidates, having passed the requisite examinations, were admitted Fellows: T. W. Carroll, M.B., B.S.Melb., J. L. Newton, M.B., Ch.B.Liverp., J. B. Reid, M.B., Ch.B.St. And., B. Williams, M.B., B.S.Melb.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

A quarterly meeting of the Royal College of Physicians of Edinburgh was held on February 6th, with the president, Dr. Edwin Bramwell, in the chair. Dr. Ian George Wilson Hill (Aberdeen) and Dr. Sydney Alfred Smith (Edinburgh) were introduced, and took their seats as Fellows of the College. Dr. Francis Wm. Murray Cunningham (Hove), Dr. Prem Nath Suri (Lahore), and Dr. Alex. MacAndrew Gillespie (Gold Coast) were elected Fellows.

ROYAL COLLEGE OF SURGEONS IN IRELAND

At a meeting of the President, Vice-President, and Council held on February 9th, William Norman Rae, M.A., F.I.C., was elected professor of chemistry and physics in the Schools of Surgery of the College.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The House of Lords has given a second reading to the Contraceptives Bill, introduced by Lord Dawson. The debate is reported below. The text of the Bill appeared in the *Supplement* of February 3rd (p. 54).

The House of Commons was in committee this week on the Unemployment Bill. An amendment to extend the benefits of the Bill to "black-coated workers" was defeated. Resolutions were put down for February 15th approving increased import duties on oats, oat products, and French dress goods. A Standing Committee began to examine the Bill for standardizing the hours of sale in public houses.

The Parliamentary Medical Committee met at the House of Commons on February 7th, Sir Francis Fremantle presiding. Professor Edward Mellanby spoke on the work of the Medical Research Council, of which he is secretary. Debate followed on how these researches could be linked with parliamentary action. Mr. C. Hill, Mr. Pearson, and Mr. Gamble, representing three firms of manufacturing chemists, made statements to the committee about the supply and price of insulin. They declared that the price in the United Kingdom was lower than in any other country except Denmark, which had used British methods to develop the production and export of the drug.

The Rural Water Supplies Bill was presented by the Minister of Health in the House of Commons on February 12th and read a first time. This Bill also applies to Scotland.

The report for 1933 by the inspector under the Inebriates Act was laid on the table of the Commons on February 9th.

A petition "against the increasing practice of vivisection," signed by 170,000 persons, was presented to the House of Commons by Mr. Groves on February 8th.

Sale of Contraceptives

LORD DAWSON'S BILL

In the House of Lords on February 13th Lord Dawson of Penn moved the second reading of the Contraceptives Bill, which restricts the sale, display, and advertisement of contraceptives. He said opinions on birth control and contraceptives could not be intelligibly considered one without the other. As one who had thought and written about the subject for many years, he wished at once to identify himself with the view that the way to keep the sale and use of contraceptives on sound lines was to remove the veil of doubt as to the honesty of contraception. The fact that there was a doubt as to its cleanliness and honesty prevented honest traders from taking contraceptives into their trades, and thereby the profits remained too large and the sale got into the hands of less scrupulous traders. If this slur were removed that trade would get into more normal channels. No impartial observer of events to-day could doubt that birth control was here to stay, and was part and parcel of our social fabric. At the same time there was good cause for protecting children and young persons from having contraceptives forced on their notice by automatic machines in streets or by lurid displays in shops. An investigation of the facts—and he had investigated facts—would show that in the main the wholesale trade was as respectably run as any other trade. The factories were well constructed; the workers belonged to a high class, and were well treated and well behaved. There was no justification for referring to the trade as vicious. It was condemnation which sent the sale into underground channels. The same was true of propaganda. If clinics were supported which gave information which was sane, these lurid publications would cease to be profitable.

Evidence of Birth Control

There had been a fall in the birth rate in most countries, whether Protestant or Catholic, in the Western world. If

they took the years from 1880 to 1930 they would find a decline of 54 per cent. in the birth rate in England and Wales, 43 per cent. in Scotland, 42 per cent. and 58 per cent. in Catholic Belgium and Austria, and 42 per cent. in Denmark. Turning to this country and this century, and taking the table of the birth rate per 1,000 married men under 55, there had been a steady fall in fecundity. That fall began among the professional classes. It was found first, for example, among ministers of religion, doctors, lawyers, and teachers. It then extended to people of other occupations, and it might now be said to have reached the artisan classes. There had been a legitimate fear that if there was a decline in fecundity in all these classes, except the classes of semi-skilled and unskilled labour, the result would be serious to the quality of the population. That would have been true if that fact had held. During one or two investigations there had recently been made a scientific inquiry into a group of wives of artisan and semi-skilled and unskilled citizens. That inquiry had had under its purview ten years—from 1923 to 1933. During that time there had been a total decline of the birth rate in the unskilled and semi-skilled classes of 14.4 per cent., and the decline was increasing, especially among the younger married men of 40 and under. What was more significant was that, if they took the gap or space between children in that class for that period of years, they found that the average gap had gone up by eight months. There was no surer evidence of birth control than a fall in the birth rate and an increase in the interval between children.

The sale of contraceptives had gone up almost by leaps and bounds. One firm at the present time turned out 8,500,000 articles a year, another firm dealing in contraceptives turned out 72,000 per week; and home production was reinforced by large importations from abroad. Contraceptives were now part of our social fabric, and to oppose them was to beat the air. No civil or military authority had ever succeeded in suppressing contraception. It had now been decided, for good or evil, that for economic and family reasons pregnancies should be limited, and that choice, not chance, should decide the size of the family. When told that these ends should be attained by self-control, young persons of to-day replied that they were being asked something which was new, and something which preceding generations in this country did not practise. In effect, they were being asked to practise celibacy within the state of wedlock. In the prosperous forties of the last century the Gladstones and the Lytteltons often stayed together under the same roof. In 1847, on one of those occasions, there were eleven children of the two families under 7 years of age. On another occasion there were seventeen children under 12 years. There was not much evidence of abstinence in marriage there. Human nature had not changed since the forties of last century, nor had biological laws. The foundation of the home required physical love periodically repeated, yet no one would be rash enough to say in these days that families should be of equal size to those of the last century. Take a young couple who married, the man between 24 and 25 and the girl 21. They had a modest income, and properly, after the first child, or possibly the second, made up their minds that for a period of seven or eight years they would not be able to afford any more children. That could be done by abstinence, which, as a medical man, he thought would be impossible, or would lead to irregularities and eccentricities, which were serious matters. In 1847 the infant death rate was 172, sufficiently high to act as a safety-valve; to-day the figure was down to 65. Contraception had not sprung from any evil purpose or selfish impulse; it was outrageous to say that of the young generation. Contraception was right so long as it was properly carried out, with delicacy of feeling and proper restraint.

Provisions of the Bill

The aim of his Bill was to protect the immature by preventing the obtrusive display and sale of contraceptives. For more than a year he had been watching carefully, and there was no doubt that there was an increase of the automatic machines. These were placed in thoroughfares, outside chemists' and rubber shops, and were left there when the shops were closed. In one of the largest Midland towns, outside a chemist's shop, which faced the exit of the largest factory in the town, stood an automatic machine; on one

side of the machine were divisions out of which, for 6d., could be drawn "aspros," and on the other side, for 1s., were contraceptives. Lord Dawson said that automatic machines were dealt with in Subsection A of the first clause. There was an undoubted tendency for shops which were lurid in their get-up to increase in numbers. As long as they were confined to a notorious quarter of London he would have said nothing. But there was an extension in their number, and they had an increased glamour in their presentation. Inside their windows, side by side with contraceptives, would be found illustrations and descriptions which were flamboyant and aggressive. No good purpose could be served by anything of that kind. Subsection C of the clause laid it down that it should be illegal to display contraceptives in or outside any shop so as to be visible to persons outside the shop. There was no limitation to be put on what the owner of the shop wished to put inside the shop, nor was any restriction placed on the sale of contraceptives to any person at any age. Once a person who wanted them got into the shop he was perfectly free to buy any contraceptives he desired.

It might be asked why they did not forbid the sale of contraceptives inside the shop altogether. There was nothing so foolish as trying to drag on youth. In his judgement the intervention of the resistance which the entry into the shop provided would be enough. Unless these things were thrown at the healthy youth he would not trouble much about them. Of course there were exceptions, as no one knew better than a medical man. He could spend hours telling the House the most dreadful examples of degeneracy through the use of contraceptives and over-drinking. It was a notorious thing that both in and out of marriage sex had a great tendency to run to perversion. That was one of the problems of the age. Therefore the sanest thing to do was to content themselves with doing away with obtrusive display and sale, whether in an automatic machine or in a lurid shop. Subsection D prevented the sending of circulars about contraceptives to unmarried people under 18.

If the House gave the Bill a second reading obvious amendments would be required, which he would be happy to accept provided that the principle of the Bill was not undermined. He would mention two. It was quite clear that they must exempt from the operation of Subsection B nurses, midwives, and doctors. In Subsection D magazines, newspapers, and suchlike publications would be exempted, for it would never do for a newspaper which happened to contain an advertisement of contraceptives to run any risk of being charged with an offence. He had submitted that point to his legal advisers, and if the Bill went to committee he would immediately move to add a proviso to deal with all these points.

General Debate

Lord BANBURY moved the rejection of the Bill. He said that, having listened to Lord Dawson's speech, he had come to the conclusion that he was strongly in favour of the use of contraceptives. He had spoken a few moments before to Lord Horder, also a medical man, who had authorized him to say that in his opinion the use of contraceptives was in no way injurious to health. Lord Dawson had said that birth control was here to stay, and was part of our social system; if that was so, why bring in a Bill to restrict the sale of contraceptives? If a person liked to do something which, according to Lord Dawson and other medical authorities, was not injurious to health, why on earth should he not do so? Under this Bill it would be impossible for a nurse or midwife who was visiting a poor woman whose health had been undermined by child-bearing to sell, or offer for sale, any contraceptives. He presumed the Bill would not prevent the nurse giving contraceptives. The Bill would also apparently prevent the doctor bringing contraceptives unless he gave them away. The Bishop of London said that, while he did not agree with Lord Dawson, he enthusiastically supported his Bill. Holding up a large envelope, the Bishop said: "I would ask Lord Banbury, Does he really think that there is nothing harmful in these things, which are sent to every engaged couple by these firms?" The medical profession did not at all hold the view that this indiscriminate advertisement of means of prevention was in the public interest. Viscount FITZALAN said that it was impossible for him to accept the view that the use of contraceptives was not wrong. He had a perfect horror of their use, and of the harm

and evil which he believed they were doing. But he was bound to acknowledge that the object of the Bill was to abolish certain evil things which were going on at present, and so he supported it.

The Bishop of St. Albans said that if Lord Dawson really believed that contraceptives were a gift of God through science then he should say so plainly, and should get the General Medical Council to make a pronouncement on the subject. Lord Dawson would lead them to suppose that the medical profession was unanimous in believing that the use of contraceptives was healthy, promoted happier homes, healthier motherhood, a finer race of children, and, above all, finer character. He would give them to believe that practically all the members of his profession would agree with all that. He had heard it stated by responsible people that practically the only medical men who were not in favour of birth control were members of the Roman-Catholic Communion. That he denied. There were a number of medical men whose special work had been in this line who were not members of that communion, but who held just as strongly that on grounds of health, let alone anything else, there was grave doubt of the beneficial effects of these mechanical and chemical devices for frustrating the biological end of sexual intercourse between men and women. Lord Ponsonby opposed the Bill on social grounds. He said he did not suppose it would go far, and it had no chance in the House of Commons, as there would be no time for it. The result would be that contraceptives would be sold in increased quantities. The Archbishop of Canterbury said that the Bill should be decided on its merits. Lord Dawson would not have taken the responsibility of bringing in this Bill unless he had two convictions: one that there were evils associated with the use of these contraceptives that called for restraint, and the other that this was a Bill which was in vital ways likely to set forward that object. These who regarded the use of contraceptives at all times and in any circumstances as morally wrong must acknowledge that it was impossible to prohibit the sale of contraceptives, and public prohibition in this matter would only increase the evil. In the Bill the House was dealing—it might be inadequately—with a growing evil. The widespread purchase of contraceptives was resulting all over the country in promiscuous acts of sexual intercourse among unmarried persons.

The Earl of FEVERSHAM, Lord-in-Waiting, replying for the Government, said that any Bill dealing with this question must have a strong measure of public support before it had any prospect of passing into law. The Government was strictly neutral on the Bill; it would neither support it nor oppose it. It would carefully examine the views expressed.

Lord Dawson said that after the debate he was still without the constructive alternative to his proposals for which he had so often asked.

The motion for the rejection was defeated by 45 votes to 6—majority. 39—and the Bill was read a second time.

The Sterilization Report

Sir HILTON YOUNG told Commander James, on February 8th, that he was in consultation, through the Board of Control, with the Medical Research Council and the Registrar-General as to the best course of action concerning the recommendations in the report of the Departmental Committee upon Sterilization.

Road Accidents: Suggested Remedies

In the House of Commons, on February 7th, Mr. Glossop moved a resolution about the increase in road accidents, and called for active steps to conduce to greater safety of all users of the road. He remarked upon the multiplicity of lighting authorities, and the lack of uniformity in the systems employed for lighting the same road. Captain WATT, in seconding, said England had more vehicles per mile of road than had any other country—13 motors per mile, against 3.9 in France, 6.3 in Germany, and 8.8 in the United States. In replying to the debate, Mr. STANLEY, Minister of Transport, said that in the quarter ended September 30th, 1933, 2,297,000 motor vehicles were licensed and 2,947,000 driving licences issued. He had asked the London and Home Counties Traffic Advisory Committee for a scheme of pedestrian crossing-places. He would try an experiment of "traffic lanes"

on one of the new wide by-pass roads, and also the dual track road with a continuous barrier down the middle. A special cycling track might be introduced on one of the roads near London. He had drafted a circular to road authorities which would announce that future grants for resurfacing roads would be contingent on alteration of camber and on super-elevation at bends, wherever practicable. The circular would also draw attention to the desirability of a light-coloured surface and rougher surfacing for the roads, and would ask that the surface of footpaths should not be inferior to that of the highway. He had made a grant towards a special "safety first" campaign in the coming summer. The House then adopted Mr. Glossop's resolution.

Road Accident Figures for Eight Years.—Replying to Mr. Isaac Foot, on February 7th, Sir JOHN GILMOUR gave the following table showing the number of persons killed and injured during the eight years 1926 to 1933 on the roads of Great Britain.

Year	Killed	Injured	Total
1925	4,886	113,888	138,774
1927	5,329	148,575	153,904
1928	6,138	164,839	170,976
1929	6,695	170,917	177,613
1930	7,305	177,895	185,200
1931	6,691	202,119	208,810
1932	6,667	206,450	213,117
1933	7,125	216,401	223,526
Total	50,837	1,421,083	1,471,920

Convictions under Vaccination Act.—On February 12th Mr. HACKING informed Mr. Groves that governors of prisons had standing instructions to ensure that persons committed to prison for matters connected with the Vaccination Acts were treated as first-class misdemeanants as required by Section 5 of the Vaccination Act, 1898. Such committals were rare.

Research-Workers on Chemical Defence.—Mr. DUFF COOPER told Mr. Gordon Macdonald, on February 8th, that the total staff on the approved establishment of the Chemical Defence Research Department on April 1st, 1925, 1930, and 1933 were 480, 553, and 502 respectively.

Water Supply Surveys.—In reply to Mr. Logan, on February 8th, Sir HILTON YOUNG stated that forty-four county councils had taken action in the carrying out, initiation, or co-ordination of surveys in their areas as to conditions of existing water supplies and the availability of new supplies. In addition six county councils had rural schemes under consideration. Six advisory regional committees had been formed, and measures had been taken for the appointment at an early date of two additional committees covering large areas.

Housing Progress.—Between May 1st and December 31st, 1933, local authorities and private enterprise in England and Wales erected 35,561 houses with the aid of subsidies. During the half-year ended September 30th, 1933, the same agencies erected 76,185 small houses without subsidy. Under the Housing (Financial Provisions) Act, 1933, local authorities have submitted to Sir Hilton Young plans in respect of 17,300 houses. Since May last fifty-three local authorities have secured approval of proposals for building without subsidy.

Inquiry Committees.—On February 5th Mr. HORE-BELISHA, replying to Mr. Wilmot, circulated a list of committees of inquiry appointed during the last six years which have not yet finally reported. The list includes the committee on Workmen's Compensation (Industrial Diseases), which was appointed in November, 1930. The Local Government and Public Health Law Consolidation Committee, which was appointed in December, 1930, had as its object to consider the grouping of enactments in regard to consolidated legislation. The Committee on Food Standards, to inquire into the law relating to the composition and description of articles of food, was appointed in May, 1931, and reappointed in July, 1933.

Inflammable Film with Toy Cinema Projectors.—Sir JOHN GILMOUR told Dr. Howitt, on February 8th, that he understood that the film supplied with some toy cinema projectors was of standard size and highly inflammable. Three accidents with this type of machine and film had been brought to his notice. In November last the traders concerned agreed to issue with each machine and box of film sold a notice warning purchasers to take suitable precautions against fire. Similar action was taken by firms known to be advertising film for sale. He had no power of control over the sale of inflammable film, but was making inquiry on what further action could be taken.

Poisons Act and the Sale of Barbiturates.—Replying, on February 8th, to Mr. David Grenfell, Sir JOHN GILMOUR said that the Pharmacy and Poisons Act contained no provision for the appointment of Government inspectors. Mr. Grenfell further asked what existing power there was to prevent the increasing sale of drugs of the barbituric group. Sir John Gilmour said he had no reason to suppose that the powers of control of the sale of poisons conferred by the Pharmacy and Poisons Act, 1933, would not prove adequate for this purpose. He had received information about the alleged increase in fatalities due to the use of these drugs, and hoped that the new regulations under the Act would be effective.

Obituary

D. E. CORE, M.D., F.R.C.P.

Lecturer in Neurology, Manchester University.

Donald Elms Core, the son of the late Thomas Hamilton Core, professor of mechanics in the University of Manchester, was born at Manchester on October 14th, 1882. He was educated at the Manchester Grammar School, where he showed evidence of his unusual ability by prize-taking and a liking for languages, dead and living. His medical training was received at Manchester, and he took several class prizes as well as the surgical clinical prize at the Royal Infirmary, and the Dumville surgical prize. He was awarded first-class honours in his M.B., Ch.B. examination in 1906, took his M.D., with honourable mention, in 1910, and in 1927 was elected Fellow of the Royal College of Physicians. After filling the post of house-physician at the Manchester Royal Infirmary he pursued post-graduate studies in Paris, attending the clinics of the leading physicians, including that of Babinski. On his return to Manchester he was appointed successively to the posts of pathological registrar at the Christie Cancer Hospital, house-physician at Derby Royal Infirmary, resident medical officer at the Barnes Convalescent Hospital of the Manchester Royal Infirmary, and, finally, resident medical officer in the last-mentioned hospital.

During the tenure of his last resident post he contracted a severe septicaemia from a wound on his hand whilst on holiday, and the small finger remained permanently useless in complete flexion. In 1912 he returned to Paris for a few months and carried out some work under Metchnikoff at the Pasteur Institute, on the morphology and physiology of the blood and bone marrow. Next year he was appointed an honorary physician to Ancoats Hospital and assistant medical officer to the Manchester Hospital for Consumption and Diseases of the Chest. When Mr. A. H. Burgess organized the 33rd British General Hospital for service in Mesopotamia, and staffed it almost completely with Manchester men, Dr. Core went with it as one of the physicians, against the advice of friends, who thought that he would not be able to stand the climate. Unfortunately he broke down at once with dysentery, and was invalided to India. He also had pleurisy and malaria, but recovered in six months to rejoin the unit and work with it until its year of service terminated. This breakdown under-

mined his constitution and left him with impaired health. Nevertheless he carried on with his full share of work, and was put in charge of the special neurological unit of the 2nd Western General Hospital in Manchester; he also acted as consulting specialist for nervous affections in all other affiliated units of the parent hospital. In 1917 Dr. Core was appointed honorary assistant physician to the Royal Infirmary, Manchester, and four years later joined the University staff as lecturer in neurology. His teaching was much appreciated by the students, especially when he was dealing with organic diseases. He was also an honorary physician to the Manchester Royal Eye Hospital.

In 1922 he published an elaborate monograph on functional nervous disorders, their classification and treatment. The object of the book, the preface stated, was to try to clear up the confusion and lack of agreement in the problems presented by such a subject, the importance of which had been emphasized as a result of the recent war. It was a close clinical and psychological study, and presented very novel ideas on the subject. It was too difficult for the average person, let alone the student, to master, and even experienced neurologists found that it needed very careful reading to grasp its line of argument. A few years later (1928) he published a smaller book, *The Examination of the Central Nervous System*. This was intended for the use of medical students who had not completed their training in neurology. Its scope was more elementary, and it was written in a clear and simple manner. A paper published in 1918 on some mechanisms at work in the evolution of hysteria, and another in 1925 on some clinical aspects of certain emotions, indicated his predominant interest in the study of functional nervous disease.

As consulting physician in the neurological hospitals he came into contact with many practitioners, who were much impressed by his enthusiasm for the work and his careful attention to details. This latter characteristic remained with him in his very large practice, his letters about patients sent to him being much fuller than those of any other physician. Dr. Core had an attractive personality, and was a well-read and widely informed man. He will long be remembered with regard and esteem in the medical life of Manchester.

GERARD FORD PORTER, M.D., F.R.C.S.Ed.

Medical Officer of Health and Port Sanitary Officer, Harwich. We regret to announce the death, on January 21st, of Dr. Gerard Ford Porter of Dovercourt, Essex, who was greatly esteemed as a general practitioner, and combined with that work the duties of medical officer of health, school medical officer, and port sanitary medical officer for Harwich. He was born on December 9th, 1883, in Manchester, of which city his father, the late Sir Alexander Porter, had been Lord Mayor. From Manchester Grammar School he went to the Victoria University, where he graduated M.B., Ch.B. in 1906, and M.D. three years later, obtaining the diploma of F.R.C.S.Ed. in 1912. During his undergraduate days he was captain of the Manchester University Cricket Club. Dr. Porter's early appointments included those of house-physician and accident house-surgeon at the Royal Infirmary, house-surgeon at St. Mary's Hospital, and house-physician at Ancoats Hospital, Manchester; and house-surgeon at the Ear, Nose and Throat Hospital, Birmingham. He served through the greater part of the war with a temporary commission in the R.A.M.C., his skill as an operator being recognized by appointment as surgical specialist. Since the war he had practised in partnership with his brother, Dr. Alexander Porter, at Dovercourt, and he was a J.P. for the borough of Harwich.

Mr. B. WHITCHURCH HOWELL, F.R.C.S., writes: The sudden and unexpected death, in the prime of life, of Gerard Ford Porter, F.R.C.S.Ed., came as a very great shock to the borough of Harwich and the countryside for miles around. It had been my very great privilege to have worked with him, and known him intimately, for some ten years. It did not take one long to realize his sterling qualities, both as an operating surgeon and as family doctor, philosopher, and friend. He was indeed the beloved physician. He had time for everybody, young and old, and for their problems. He found time, too, for everything: reading in all the branches of his profession and general literature, politics, travelling, music, games. The Harwich and Fryatt Memorial Hospital owed its fine modern site, building, and equipment to the foresight and enthusiasm of Gerard Ford Porter. It was the apple of his eye, and, in consequence, the centre of surgical and medical practice for miles around. "Friar Tuck" he was to some of us, and his jolly smile, his jaunty step, his ever-present optimism, will ever be remembered.

CHARLES ATKIN, F.R.C.S.

Consulting Surgeon, Sheffield Royal Infirmary

Mr. Charles Atkin, formerly well known as a prominent Sheffield surgeon, died on February 2nd, after an accident. His father was Surgeon Major G. Atkin, and one of his grandfathers was Alderman John Carr, also a surgeon and Mayor of Sheffield. He was educated at Hildesheim Gynnasium, at Sheffield, and at Guy's Hospital, and after qualifying M.R.C.S., L.R.C.P. in 1880 he studied at clinics in Vienna. His early appointments included those of house-surgeon at the Sheffield Royal Infirmary, senior demonstrator in anatomy at University College, Sheffield, and house-surgeon to the Liverpool Eye and Ear Infirmary. In 1884 he became a Fellow of the Royal College of Surgeons of England. Later, on being elected to the surgical staff of the Sheffield Royal Infirmary, he became lecturer on pathological anatomy and demonstrator of practical surgery in the University College. When he retired from the active work of the hospital he was elected consulting surgeon.

For more than thirty years Mr. Atkin was a member of the British Medical Association, and at the Annual Meeting at Sheffield in 1908 he held office as vice-president of the Section of Surgery. He married Alice, daughter of Professor Brady, and had two sons and one daughter.

Dr. BERNARD HOLLANDER, who was very well known to the public through his writings and lectures on mental and nervous derangements, died in London on February 6th at the age of 70. A native of Vienna, he came to England at the age of 19, and studied medicine at King's College Hospital, qualifying M.R.C.S. and L.R.C.P. in 1898. He was for some time an assistant at Krafft-Ebing's psychiatric clinic in Vienna, and studied also at the University of Freiburg, where he obtained his M.D. degree. In 1899 he became naturalized as a British subject, and joined the British Medical Association. With an active and inquiring mind and great fluency of tongue and pen, Dr. Hollander won high regard in lay circles as a popular interpreter of psychopathology. He described himself as one of the foremost exponents of psychotherapy and as the founder of a modified system of phrenology on strictly scientific lines. He was also founder and president of the Ethological Society, which took its name from J. S. Mill's definition of ethology as "the science of character." His work in more prosaic fields had included that of a medical officer under the Mental Deficiency Act for the county of London, and physician to the British Hospital for Functional Mental and Nervous Disorders (Forbes Winslow Memorial) in Camden Road.

The death took place at his residence in Brighton, on February 10th, of GEORGE CHARLES LOUIS VINTRAS, B.Sc. Paris, M.D. Durh. He was born in London sixty-nine years ago, son of Dr. Achille Vintras, founder of the French Hospital and Dispensary in Shaftesbury Avenue, and of the French Convalescent Home at Brighton. Louis Vintras was educated in France and England, and spoke and wrote French, and English with equal facility. He received his medical education at St. Mary's Hospital, qualifying M.R.C.S., L.R.C.P. in 1890. He was a Knight of the Légion d'Honneur, and a Knight and Officer of the Order of the Lion and Sun of Persia, and also held the medal of King Albert of Belgium. He was consulting physician to the French Hospital and director of the French Convalescent Home in Brighton for twenty-one years, from 1907 to 1928. In his earlier years he travelled extensively as medical officer in the Royal Mail Steam Packet Company. Service in the West Indies and South America, and he also was medical officer to H.M. Transport *Tagus* in the Boer War. During the Great War Dr. Vintras was commandant and medical officer to the French Convalescent Home and Auxiliary Hospital in Brighton. He had also been assistant secretary to the French delegates at the Congress of Hygiene and Demography in London, 1891, and was physician to the Société des Gens de Lettres. He was for some years a member of the British Medical Association, and had contributed many articles to English and foreign medical journals. Dr. Vintras was possessed of a very charming personality, and when just over a year ago he recognized the fatal character of his illness, his courageous acceptance of the inevitable and his cheerful demeanour throughout were a source of admiration and inspiration to all who came across him.

The Services

DIRECTOR-GENERAL A.M.S.

The War Office announces that Major-General J. A. Hartigan, C.B., C.M.G., D.S.O., M.B., Honorary Physician to the King, at present Deputy Director of Medical Services, Aldershot Command, has been appointed Director-General, Army Medical Services, with effect from March 1st, 1934, in succession to Lieut.-General Sir Harold B. Fawcus, K.C.B., C.M.G., D.S.O., D.C.L., M.B., Honorary Physician to the King, who is retiring at his own request.

Medical News

The Rickman Godlee Lecture will be delivered in the Great Hall of University College, London, to-day (Friday, February 16th). The lecturer is Sir Arthur Eddington, F.R.S., Plumian Professor of Astronomy, University of Cambridge, and his subject "The Constitution of the Stars." The chair will be taken at 5.30 p.m. by Lord Dawson of Penn.

Dr. R. G. Canti will give an address and cinematograph demonstration on "The Cultivation of Living Tissue" to the Metropolitan Counties Branch of the British Medical Association at B.M.A. House, Tavistock Square, on Tuesday, March 6th. Members will be received by the president of the Branch, Dr. C. F. T. Scott, at 5 p.m.

The next quarterly meeting of the Royal Medico-Psychological Association will be held at 11, Chandos Street, W., on Thursday, February 22nd, at 2.30 p.m., when Dr. T. Lindsay will read a paper on "Mental Deficiency at Caterham."

The annual meeting of the Industrial Health Education Society will be held at Lord Luke's house, 29, Portman Square, W., on Wednesday, February 28th, at 4 p.m. The speakers will include Lord Horder, Sir Thomas Oliver, and Mr. George Hicks, M.P., secretary of the Building Trade Workers' Union. All communications in regard to the work of the society should be addressed to the secretary, Tavistock House North, Tavistock Square, W.C.1.

The next meeting of the Royal Microscopical Society will be held at B.M.A. House, Tavistock Square, W.C., on Wednesday, February 21st, at 5.30 p.m., when papers will be read by Professor R. Tanner Hewlett, and Mr. J. E. Barnard and Mr. F. V. Welch.

At a meeting of the Medico-Legal Society at 11, Chandos Street, W., on February 22nd, at 8.30 p.m., a paper will be read by Sir Lancelot Sanderson on law and order and medicine in India in the future, to be followed by a discussion.

The next course of post-graduate lectures and demonstrations on medical, surgical, and special subjects, given by the honorary staff of the Manchester Royal Infirmary, will open on Tuesday, February 20th, and will continue each week (with the exception of April 3rd) till May 15th. The demonstration of clinical cases and methods in the wards and special departments, which commence on Friday, February 23rd, will be continued till Friday, May 11th (with the exceptions of March 30th and April 6th). There is no fee, and arrangements are made for the parking of cars.

The Fellowship of Medicine and Post-Graduate Medical Association (1, Wimpole Street, W.) announces that the sixth lecture-demonstration, by Dr. Clark-Kennedy, on diarrhoea, will take place at 11, Chandos Street, on February 20th, at 2.30 p.m. The subject of the seventh lecture, on February 27th, will be jaundice. A demonstration on the treatment of recent and old fractures will be given on February 27th, at 2.30 p.m., by Mr. Alan Gairdner, at St. George-in-the-East Hospital. Forthcoming courses include medicine, surgery, and gynaecology at the Royal Waterloo Hospital, March 5th to 24th; proctology at the Gordon Hospital, March 5th to 10th; week-end course in clinical surgery at the Royal Albert Dock Hospital, March 10th and 11th; orthopaedics at the Royal National Orthopaedic Hospital, March 12th to 24th; week-end course in diseases of the chest, March 24th and 25th, at the Brompton Hospital. Courses of instruction, clinics, etc., arranged by the Fellowship are open only to members and associates.

At the annual meeting and luncheon of the Institute of Child Psychology, held on February 8th at the Florence Restaurant, the directors, Dr. Margaret Lowenfeld and Dr. Ethel Dukes, gave an account of the work done at the Institute in the investigation and treatment of the psychological disturbances of childhood. Begun in a small way in 1928 as a centre for research and study, the increasing demands upon the Institute led to the acquisition of new and larger premises at 26, Warwick Avenue, W.9. Among those present at the luncheon, over which Professor Winifred Cullis presided, were Lady Glenconner (vice-president), Dr. G. E. Oates, medical officer of health, Paddington, and Miss M. C. L. Greaves, Board of Education.

A demonstration of contraceptive methods, for medical practitioners only, will be given at 108, Whitfield Street, Tottenham Court Road, W., on February 21st, at 2.30 p.m. Application for tickets should be made in writing to the honorary secretary, C.B.C., at that address.

At the annual meeting of the American Association of Oral and Plastic Surgery held at New York last November, Dr. J. P. Webster delivered an address on Gaspare Tagliacozzo, the father of plastic surgery.

The issue of *Paris Medical* for January 27th contains the English text of the four bulletins written in pencil by Major Archibald Arnott, surgeon to the 20th British Regiment, at Napolcon's deathbed, and now in possession of M. Gentili de Giuseppe.

January 29th was the centenary of the birth of the celebrated physiologist Rudolf Heidenhain, who died on October 13th, 1897.

The following bequests are included in the will of the late Mr. Samuel Taylor, of Acocks Green, Birmingham: £5,000 each to the General Hospital, Birmingham; Queen's Hospital, Birmingham; the Children's Hospital, Ladywood Road, Birmingham; Birmingham Midland Eye Hospital, Church Street, Birmingham; Birmingham and Midland Ear and Throat Hospital; and Birmingham Midland Skin and Urinary Hospital.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and **LETTERS** forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring **REPRINTS** of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to **ADVERTISEMENTS**, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBER** of the British Medical Association and the *British Medical Journal* is **EUSTON 2111** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Aitology
Westcott, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER
(Advertisements, etc.), *Articulate Westcott, London.*

MEDICAL SECRETARY, Medisecra Westcott, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumshugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Calot's Solution

"G. B." writes: In the *Epitome of Current Medical Literature* for February 3rd, Calot's solution is mentioned for the treatment of otorrhoea. I should be glad to know the exact prescription.

* In Martindale's *Extra Pharmacopoeia*, 20th edition, 1932, the following note appears at p. 655: "*Creosoted Oil* (Calot's formula). Liquid paraffin 70 gm., sterilized by boiling for $\frac{1}{2}$ hour. Allow to cool, and add in order (1) creosote 5 gm., (2) guaiacol 1 gm., (3) iodoform (sterile) 10 gm., (4) ether 30 gm. Used as a wound dressing."

Mental Allergy

Dr. P. LIONEL GOITEN (London, W.) writes: Possibly the causal process for certain irrational fears mentioned by "A. G." (January 13th, p. 88) aroused, in the predisposed, alike by animate and inanimate objects, is not so much an hereditary allergic state (idiopathy or eccentricity) as a conditioned reaction to a certain situation. It is not the object that is deleterious, but the idea of the object. The analogy to bodily "shock" in response to something foreign to its nature is strengthened when we remember the asthmatic's "attack" to artificial flowers and the acrophobe's "cold sweat" at the mere mention of the objects of his dread. "A. G.'s" paræsthetic sensation to saw-sounds is, of course, analogous to the "cold shivers" down the spine in many grown-ups at the screech of glass, the scratch of the nail on shiny paper, the whine of grating china, etc. This is often found to be a survival of that period of growth when the mind endows all objects indiscriminately with feeling, and the infant "empathizes" with the glass, etc., as a result, believing its shriek to be the cry of pain in response to actual or threatened injury. The stage of animism in mental evolution (when the feelings are considered to be shared by the object) has its counterpart in the projection of fears on to external objects—for example, the fear of the little thing—as terror at the (innocuous) frog, mouse, worm, etc., a well-nigh universal phenomenon before objects of symbolic import to the unconscious of the race. Such an hereditary feature, then, would explain, for the species as well as for the race and individual, "A. G.'s" quoted anomaly—namely, the hysterics of the chimpanzee, the taboos of the savage, and the idiosyncrasies of certain of his patients.

Income Tax

Remittances from Abroad in Payment of Expenses

"OVERSEAS MEMBER" inquires whether his brother, who is executor for his deceased sister, is liable to tax in respect of remittances sent to him by "Overseas Member" in payment of expenses incurred by the brother as executor.

* The remittances would not seem to represent income either to the deceased sister's estate or to the brother, and we can see no ground on which they would be held

liable to income tax. They seem to be merely repayment of sums spent in connexion with capital, and, as such, outside the scope of the Income Tax Acts.

LETTERS, NOTES, ETC.

Study of Chicken-pox and Herpes Zoster: Request for Material

The director of the Lister Institute of Preventive Medicine will be grateful if doctors or medical superintendents of hospitals or institutions in the London area, and not too remote from Chelsea, who have such cases under their charge and are willing to give facilities for access to such cases (to secure material from earliest varicella vesicles and small samples of blood), will communicate by letter, postcard, or telephone with Dr. C. R. Amies, the Lister Institute, Chelsea Bridge Road, S.W.1 (Slance 2181).

Procreation after Prostatectomy

Dr. CHARLES P. MATIÉ (San Francisco) and Dr. EMILIO DE LA PEÑA (San Francisco and Madrid) write: We have read with great interest Mr. Alex. E. Roche's comments (*Journal*, November 11th, 1933, p. 904) on our recent article (abstracted in the *Epitome*, November 4th, 1933, para. 315) in reference to the improbability of procreation after transurethral resection of the prostate, and his statement that "there is no advantage from the procreative point of view in transurethral, as opposed to suprapubic, prostatectomy." In an article by us in the *Urologic and Cutaneous Review* (1933, xxxvii, 156) we stated that "increase in sexual power was observed in many cases and integrity of the procreative power was preserved." This statement was apparently distorted in the translation of this article into Spanish for publication in the *Arch. Med., Cir. y Esp.*, from which the abstract referred to by Mr. Roche was made. If your readers will refer to our original articles they will learn that on account of the very low mortality connected with transurethral resection of the prostate (less than 1 per cent. in our hands) it is now being applied to an increasing number of men who are approaching the prostatic age, and in whom prostatic hypertrophy is detected in its earliest stages, before infection, stasis, and decrepitude have shown themselves. As recession of the gland has been observed to occur following transurethral resection, this operation can be considered as a preventive measure against urinary retention of old age. Few men will refuse this relatively benign closed operation—many men, at least those in America, have suffered from prostatism, dreading prostatectomy for years, and finally accepting the operation only when the obstructive symptoms have become intolerable. This group of early cases contains a few men in the forties; a larger number in the fifties and early sixties. A large percentage of these men are in the age of sexual activity, and in this group a properly performed resection in which the integrity of the internal sphincter has been respected does not necessarily destroy procreative capacity. We naturally assumed that it would be understood by all our readers that in referring to procreation we were not considering the decrepit septuagenarians and octogenarians, weakened by years of suffering and threatening uræmia, who, if married, usually have wives beyond the child-bearing age. In the majority of these cases it is our procedure to perform a preliminary vasectomy in order to prevent the unpleasant complications of epididymitis. Procreation is of importance to the early cases of prostatic hypertrophy, which are treated by transurethral resection. For the above reason we shall feel that our statement in reference to procreation was well worth making and worthy of consideration.

Disclaimer

Mr. S. W. Daw, F.R.C.S., writes: My name has been mentioned in certain newspapers in connexion with a case treated at Leeds Infirmary. I wish it to be made known that this use of my name was entirely unauthorized and without my knowledge.

Book-keeping for the G.P.

A typographical error appeared in our note under this heading (February 3rd, p. 224). Referring to Dr. Rowthorn's "slips" we stated that these took the place of "day-book, prescription book, and waiting list"—this last should, of course, read "visiting list."

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 49, 50, 51, 52, 53, 56, and 57 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 54 and 55. A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 72.

PROPRIETARY REMEDIES, WITH SPECIAL REFERENCE TO HYPNOTICS*

BY

N. MUTCH, M.D., F.R.C.P.

PHYSICIAN, GUY'S HOSPITAL; LECTURER AND EXAMINER IN PHARMACOLOGY, LONDON UNIVERSITY

Proprietary remedies far outnumber official ones. Their definition, which presents some difficulty, is given by the American Medical Association as:

"Any chemical, drug, or similar preparation used in the treatment of diseases, if such article is protected against free competition as to name, product, composition, or process of manufacture by secrecy, patent, or copyright, or by any other means."

Many are substances of genuine merit, but the dubious devices employed by certain proprietors to promote the sale of their particular drugs engender feelings of resentment and suspicion among the medical profession in respect of all. The following blatant methods are in common use: the application of a registered name to a pharmacopoeial drug and its sale to the public in an attractive packing; the exploitation of the mystery of vitamins and radium as a means of selling mixtures containing, in addition, analgesic, stimulant, or aperient drugs; and the obfuscation of the medical man himself by plausible, pseudo-scientific trade literature adorned by fantastic chemical nomenclature.

The present object, however, is to extol the virtues of ethical remedies, not to discuss the black sheep of pharmaceutical exploitation. One of the greatest tributes paid to those who devise new drugs and patent them is the official adoption of drugs of proprietary origin in later editions of the *British Pharmacopoeia*. Methyl sulphonal was patented in 1888 as a sulphonal derivative of greater solubility and speedier hypnotic action than the parent substance. It was sold as trional, but soon found its way not only into the *British Pharmacopoeia*, but into those of Belgium, Holland, America, and Japan. Barbitone itself had a similar origin, and was introduced under the registered name veronal in 1903. Nowadays it is official in the leading pharmacopoeias throughout the world. Soluble barbitone, patented in 1904 as medinal (Schering), is enjoying a similar career, and has just been introduced into the new 1932 edition of the *B.P.* So it has been with heroin, dionine, atophan, stovaine, and a host of other products.

RESEARCH BY COMMERCIAL FIRMS

Facilities for pharmacological research in our universities and medical schools are very limited indeed. During the last half-century attention has been focused on anatomy, physiology, and pathology, but pharmacology and experimental therapeutics have been neglected, although they have a direct vocational bearing and supply the true link between the academic knowledge of the non-practising medical scientist and the everyday needs of the busy practitioner. This neglect is largely responsible for the mental dissociation which takes place between knowledge acquired laboriously in undergraduate days and that used directly for the benefit of the patient. The legitimate demand of the practitioner for new tools and drugs has in the past largely been met by firms interested financially in the sale of their products. Large sums have been diverted from their dividends into the channels of research. It would be more in keeping with the dignity and traditions of the profession if independent pharmacological research could be endowed in our medical schools and universities sufficiently well to enable us to

make our own discoveries. We ought not to be under so great an obligation to the manufacturers of proprietary remedies in this matter. The discriminating work on the active principles of ergot carried out by Sir Henry Dale and his co-workers in the Wellcome Research Laboratories² is an outstanding example of important advances made under the direct aegis of commercial concerns. Such firms exert a powerful influence on post-graduate teaching. It is a good policy to interview travellers from important drug houses and scan the literature with which they burden the breakfast table. In this way there can be acquired much useful knowledge which is not imparted in the lecture rooms and wards. The simplicity and reiteration of their statements register in memory and practice more effectively than does logical exposition before learned societies or in scientific journals.

Vegetable mucilages, such as those of linseed, psyllium, and ispaghula, have long been employed in gastro-enterology, but as a class they never enjoyed any great vogue in this country until some difficulties of administration were overcome and house-to-house instruction in their properties undertaken by Messrs. Napp and Co. in their efforts to sell a particular brand of dried mucilage as normacol. The practical importance of this type of therapy is now common knowledge throughout the profession.

The physical process of adsorption had been known and widely used in general commerce and in chemical research long before the century began. It is highly improbable, however, that in 1914 even one practitioner in a thousand realized that it could be applied advantageously in the treatment of alimentary conditions. Now, thanks largely to the educational value of trade literature, adsorption by china clay and kindred products is made use of daily by a large proportion of the profession to purify infected and putrescing material in the stomach and intestines. It has become a fundamental therapeutic principle in dealing with intestinal toxæmia and poisoning from contaminated food.

Palatability, elegance, convenience, and painlessness all call for a type of research for which the medical man has little time to spare, but they are essential to success and the special concern of those who manufacture under patents and registered names. It is useless to prescribe unless the patient will consume. The tablet has made the midday dose so easy that the business man and the patient who is out all day have now no excuse for omitting it. The earlier forms of injectable iron made up to prescription provoked a local reaction so painful as to prohibit their use. Proprietary solutions, such as Messrs. Roberts and Co.'s ferrigen or Fraisse's ferruginous serum, were painless and essential. Now at last a painless injectable iron preparation has been introduced in the new *B.P.*

VALUE OF A "BRAND" NAME

Sale under a brand name has much to be said in its favour. The quality even of *B.P.* products sold by large firms under their brand name is often maintained by systematic tests of a far more discriminating nature than those laid down in the *Pharmacopoeia*. Until a year ago medicinal paraffin could be sold as conforming to *B.P.* standards even if its specific gravity was as low as 0.869. Samples of light oils of this nature were on sale in all parts of the country, but they were useless for lubrication

* Based on addresses read before the Kent Branch and the Kensington Division of the British Medical Association.

at body temperature. It would have been far more rational to use Arctic grade motor oil in the Tropics than to employ these light-grade medicinal oils in the intestine. Several firms, applying the principles of engine lubrication, marketed high specific gravity paraffin only. Their wisdom receives recognition in the 1932 B.P., where the low limit for these oils is now raised to 0.880. Until last autumn, however, it was most important to specify a proprietary brand of known high viscosity or stipulate on the prescription a definite specific gravity.

In dealing with a substance like medicinal charcoal, which does not now find a place in the B.P. at all, the question of brand is of greater importance still. The curative virtues of charcoal are determined by its power of adsorbing deleterious substances from solution in septic exudates or in the contents of the bowel. Using methylene-blue as the substance to be adsorbed and comparing the adsorptive powers of thirty samples of medicinal charcoal from various sources, I recently found astonishing variations in the potency of different brands. At one end of the scale were really effective brands of a potency undreamt of a few years ago, such as Merck's with a coefficient of 85 on my private scale, and Bayer's 75 and Gideon Richter 56; whilst at the other end were relatively feeble products, such as chardox, coefficient 9; Fraudin, 2.5; and Bragg's charcoal biscuits, 0.5. In this particular respect, therefore, Merck's product was 170 times as active as Bragg's, weight for weight. The wholesale prices varied widely from 15s. to as much as £67 4s. per cwt. Here clearly are great opportunities for the exploitation of weak inexpensive charcoals on the reputation of the more active ones. The only practicable safeguard for the busy doctor in this and similar instances is to shield himself behind the brand name of some firm of high repute.

New drugs evolved in subsidized laboratories are often costly, but this is not always the case. On occasion such researches save the patient's pocket materially. Originally adrenaline obtained from the gland itself was far more active than synthetic adrenaline produced in the laboratory. The two products had identical formulas, but the natural substance was laevorotatory and the synthetic an optically inactive isomer. In 1923 the laevorotatory form was synthesized in the laboratory of the Society of Chemical Industries at Basel for sale as adrenaline "ciba." After exhaustive tests the synthetic product appears to be identical quantitatively and qualitatively with the natural substance, and finds a place in the new B.P. The discovery prepared the way for a great reduction in the price of a costly substance in common use. It is a pleasure to record this example of an expensive proprietary research which resulted in so substantial a reduction in the retail price of an important drug.

Hypnotics

The ingenuity of manufacturing and distributing firms in inventing new drugs, modification of drugs, copies of old ones, mixtures of old and new, and in registering fresh titles for all threatens the busy man's clarity of mind. Almost every post introduces a new name. A directory is needed urgently which will summarize the chemical and therapeutic associations of these substances in a readily accessible manner. The case of our modern hypnotics can be taken as typical of the chaos with which the profession is threatened.

In recent years proprietary research has been very active among the derivatives of urea. Indeed, few pharmaceutical firms of standing have failed to appropriate at least one of these substances for exclusive sale. The search has been stimulated by the hope of finding safe hypnotics free from the heart-depressant action of the

chloral group; the offensive odour and bulky fluidity of paraldehyde; and the sluggishness, hang-over, and cumulation of sulphonal and its derivatives. Three types are needed—namely, substances suitable for inducing a night's sleep, those possessing additional power of pain relief, and others adapted for basal anaesthesia.

MODIFICATIONS OF BARBITONE

Barbitone has been an object of special interest in these researches, not because it is free from drawbacks, but because of its chemically plastic molecule. A large series of modifications has been evolved, including many substances of great utility (see Table I).

TABLE I.—Barbituric Hypnotics

Allurate (in allonal)	Allyl (isopropyl) barbituric acid	C_6H_5 C_6H_5 } B
Amytal	Isoamyl ethyl B	C_6H_5 C_6H_5 } B
Amytal soluble	Sodium amytal	C_6H_5 C_6H_5 } B_{Na}
Barbitone	Diethyl B	C_6H_5 C_6H_5 } B
Barbitone soluble	Sodium barbitone	C_6H_5 C_6H_5 } B_{Na}
Butobarbital	Butylethyl B (see soneryl, neonal, and soporigene)	C_6H_5 C_6H_5 } B
Dial	Diallyl B	C_6H_5 C_6H_5 } B
Ervipan	N-methyl C.C. cyclohexenyl, methyl B	C_6H_5 } C_6H_5 C_6H_5 } B
Gardenal	Phenylethyl B (see luminal and phenobarbital)	C_6H_5 C_6H_5 } B
Hebaral sodium	Sodium hexylethyl B	C_6H_5 C_6H_5 } B
Ipral	Calcium ethyl, isopropyl B	C_6H_5 C_6H_5 } B_{Ca}
Luminal	(See gardenal and phenobarbital)	
Modinal	(See barbitone soluble)	
Nembutal	Sodium ethyl isomethylbutyl B	C_6H_5 (C_6H_5) } B_{Na} C_6H_5
Neonal	(See butobarbital)	
Noctal	Brompropenyl isopropyl B	C_6H_5 C_6H_5 } B
Pentobarbital	(See nembutal)	
Pernocton	Sodium butyl bromallyl B	C_6H_5 } B_{Na} C_6H_5
Phanodorm	Cyclohexenyl ethyl B	C_6H_5 C_6H_5 } B
Phenobarbital	(See gardenal and luminal)	
Prominal	N-methyl ethyl phenyl B	C_6H_5 } C_6H_5 C_6H_5 } B
Proponal	Dipropyl B	C_6H_5 C_6H_5 } B
Sandopal	Isopropyl allyl B	C_6H_5 C_6H_5 } B
Soneryl	(See butobarbital)	
Soneryl sodium	Sodium butyl ethyl B	C_6H_5 C_6H_5 } B_{Na}
Soporigene	(See butobarbital)	
Veronal	(See barbitone)	

These are all modified barbituric acids conforming to the general formula C_2H_5
 C_2H_5 } **B**, where **B** stands for the barbituric nucleus and is constant, but the ethyl groups are replaceable by this, that, and the other. With every change in these ethyl groups a new barbiturate is born.

If a phenyl group C_6H_5 is used to replace one of the ethyl groups the drug seems to acquire special depressant power over the motor cortex. Such drugs can be used in epilepsy: luminal and prominal.

If sodium is added to the "B" nucleus without disturbing the essential ring formation the product becomes soluble. This confers greater speed in action—for example, barbitone sodium or medinal is far more soluble and quicker in action than simple barbitone or veronal. Solubility also makes it possible for one to inject the drug. Most of the basal anaesthetics are sodium compounds—for example, soneryl is a sleep-producer. Soneryl sodium, being more soluble, can be injected as a basal anaesthetic. Amytal sodium, evipan sodium, pernocton, and nembutal itself are all compounds of this class.

In the stage of intoxication which precedes narcosis susceptible patients show excitement. Almost everyone must on occasion have given soluble barbitol and produced a state of excitement which has hindered rather than promoted sleep. The preventive for such trouble is a preliminary dose of bromule. In certain cases, therefore, bromine has been introduced into the barbiturate nucleus—for example, noctal, pernocton.

AMIDOPYRINE AND BARBITURATES

Attempts to confer pain-relieving qualities on the barbiturates have not been very successful. The closest approaches to a solution which have been made up to the present are the association of a barbiturate nucleus with amidopyrine in Pfeiffer's compound, used in veramon, and the linkage with a member of the morphine group in didial and codonal. Amidopyrine, a derivative of antipyrine, is well known under the registered name of pyramidon, and appears to possess greater analgesic properties than antipyrine itself or other members of the simple coal-tar group. Its pain-relieving powers are enhanced by admixture with a simple hypnotic, possibly because the latter diminishes the patient's anticipation of pain. This fact has been made use of in a popular modern series of pain-relieving mixtures which fall outside the Dangerous Drugs Acts (see Table II).

TABLE II.—Analgesics Based on Amidopyrine

Allonal	= Amidopyrine + a barbiturate
Asciatine	= " + butyl chloral
Ciblgin	= " + a barbiturate
Compral	= " + a urethane
Optalidon	= " + a barbiturate
Somnosol	= " + bromural
Veramon	= " + barbitone
Veropyron	= " + barbitone

In each case pain relief is due to amidopyrines combined either mechanically or molecularly with a simple hypnotic. A barbitone derivative with pain-relieving qualities in its own right is still to be found.

DERIVATIVES OF MORPHINE

Research has also been active among the derivatives of morphine with the object of securing pain relief without causing either constipation or addiction. The bowel difficulty has largely been overcome, but it has proved impossible to dissociate addiction from the analgesic qualities of these drugs. All substances of this group with any powerful control over pain are therefore still controlled by the Dangerous Drugs Acts. They may be placed in two therapeutic groups: those akin to morphine in their control of pain, and those resembling codeine in that their analgesic properties are feeble and their utility confined to the relief of cough (Table III).

TABLE III.—Morphine and Codeine Group

For Pain	For Cough
Acetone	Codeine or methyl morphine
Dicodid	Dionine or ethyl morphine
Dilaudid	Eucodene
Eukodol	Paracodin
Heroin and morphine	(Free from the D.D.A., but
(All under the D.D.A. regulation)	of no real utility as anal-
	gesics)

HYPNOTIC CREDENTIALS

The credentials of every new hypnotic should be carefully examined before a single dose is prescribed.

Is It a Barbiturate?

No one who is familiar with Sir William Willcox's¹⁶ work on this group of drugs can fail to realize the great harm which can follow the repeated use of many members of this class. Unfortunately, the manufacturer often cloaks the description of his drug with complex chemical terms which mean nothing to most of us. For example, dial is diallyl barbituric acid, and if so described is recognizable at once as a barbitone derivative. It can also be correctly described as diallyl-malonyl-urea. It must be remembered, therefore, that all malonyl-ureas are barbitone derivatives. If, however, the firm which markets this drug describes it as 2, 4, 6, trioxo-5-diallyl-pyrimidine, what can we do? The description is correct, but none except a research chemist specializing in the organic branch would recognize it as a barbiturate.

There are many urea derivatives other than the malonyl-ureas, and some are first-class hypnotics. They are not barbiturates and are particularly useful for patients with idiosyncrasies and for those who have become habituated to barbiturates (see Table IV).

TABLE IV.—Urea Derivatives (Not Barbiturates)

1. Carbromal, now B.P. and sold as adalin, nyctal, planadalin, uradal.
2. Bromural or dormigene
3. Sedormid

The Margin of Safety

The actual potency does not concern us much. It is just as easy to give five grains of one drug as one grain of a more potent one. The point of practical importance is the margin of safety between the hypnotic dose and the lethal one. This is represented by the ratio M.L.D./M.Th.D. The higher this figure the safer the drug. Quoting from the literature:¹⁷ luminal is 1.3; barbitone 1.6; soneryl, nembutal, and phanodorm, 2.4; dial, 2.5; evipan, 5. From this it would appear that it is not very safe to employ luminal in full hypnotic doses, although in sedative or anti-epileptic dosage it is free from immediate risk.

Duration of Sleep to be Expected

The effect of a sleeping draught should last many hours, but die away before morning. For a basal anaesthetic a much shorter duration is desirable. Quoting once more from available literature:—Human therapeutic dosage: evipan sodium intravenous lasts twenty minutes, and evipan by mouth two hours. Rats' with coma dosage: nembutal, four and a half hours; pernocton, five hours; amyral, six to thirty hours; luminal, dial, and allurate, eighteen to twenty-four hours; barbitone, eighteen to thirty-six hours. The duration of narcosis produced by the dial group lies between the evanescent basal anaesthetics and that of drowsy barbitone itself. As judged by these two considerations of safety and duration alone the basal anaesthetics of choice are evipan and nembutal. Practical experience appears to justify this conclusion.

How Quickly will the Patient go to Sleep?

It is impossible to foretell whether preliminary excitement will occur during the intoxication phase or not. The question can only be answered after therapeutic trial. The speed with which hypnosis will be induced

can, however, be surmised from the solubility of the substance. If a quick effect is desired a barbiturate containing sodium should be used.

Hang-over and Cumulation

The questions of hang-over and cumulation depend upon the completeness with which the drug is dealt with by excretion or detoxication over periods of eight and twenty-four hours respectively. They are best determined by therapeutic trial, but the laboratory data are of interest. Barbiturates meet with various fates after ingestion. Some are re-excreted, others are broken down, and others disappear mysteriously. Frethwurst, Halberkann, and Reiche⁶ could recover 75 per cent. of a given dose of barbitone from the urine, 65 per cent. of pernocton, only 30 per cent. of dial, between 10 and 40 per cent. of luminal, and no amytal or neonal at all. Evipan is said to be metabolized completely in a few hours. Clearly urine analysis alone does not yield any reliable index of the probability of hang-over. Cumulation is more easily determined, especially if the drug is recoverable in part from the urine. Barbitone is known to be a serious offender, and the following analyses⁷ furnish the chemical explanation of the defect: only 8 per cent. appears in the urine in the first twelve hours; 20 per cent. in the first twenty-four; 36 per cent. in the first forty-eight; and traces can be found for as long as nine days after a single dose.

A number of other important points are only decided after the drug has come into wide use and experience has accumulated. Toxic effects may arise, due not so much to the cumulation of the drug in the tissues as to the summation of its effect on the tissues. Mental impairment and the motor paralysis following luminal are examples of this kind of trouble. The range of possible idiosyncrasies and the degree to which the patient is exposed to the risks of addiction are only discernible after the drug has been in use for years.

TABLE V.—Some Hypnotic Mixtures

Alepsal	= Phenobarbital, belladonna, and caffeine
Beotal	= Barbitone, valerian, and hyoscyamus
Belladonal	= Phenobarbital and the alkaloids of belladonna
Bromidia	= Chloral bromide and hyoscyamus
Bromovalerianate	= Chloral bromides and valerian
Brosedan	= Bromide and yeast
Indonal	= Barbitone and cannabis indica
Neurinase	= Soluble barbitone and valerian
Theogardenal	= Butobarbital and theobromine
Veromidia	= Soluble barbitone and passion flower

PRACTICAL SUGGESTIONS

1. The rejection for general use of any proprietary preparation which is merely a mixture of old familiar friends. It may be appropriate when circumstances are exceptional.

2. The rejection of any proprietary preparation exploiting the pain-relieving properties of amidopyrine and other coal-tar analgesics. These parent substances can be prescribed from the B.P., with the addition, if desirable, of the hypnotic of individual choice. Similar rules could be formulated on a rational basis in all branches of this subject of the proprietaries. If universally adopted they would spare the memory a great and daily increasing burden.

BASAL ANAESTHETICS AND ALLIED SUBSTANCES

THEIR USE AND MISUSE*

BY

H. W. FEATHERSTONE, M.A., M.D.,

HONORARY ANAESTHETIST, GENERAL, CHILDREN'S, AND MATERNITY HOSPITALS, BIRMINGHAM; LECTURER ON ANAESTHETICS IN THE UNIVERSITY OF BIRMINGHAM

The group of anaesthetic agents to which a great deal of attention has been drawn in the last few years are solids which are administered to the patient in solution in water. They provide a contrast to the well-known anaesthetic gases which are absorbed through the lungs. In this paper the attempt is made to discuss this group of non-inhalational narcotics, many of which, in view of the incomplete nature of the anaesthesia they produce when given in safe doses, have been termed "basal anaesthetics."

Although a great deal has been written on the subject by manufacturers, anaesthetists in this country have not yet offered discriminating criticism to any large extent. The medical profession and the public owe much of the progress of therapeutics in modern times to the research departments of the great drug and chemical manufacturers; but it is very necessary that judgement on the relative values of the products which these important firms offer should be dispassionate in order that, in a particular condition, the most suitable drug may be selected. To read a short excerpt quoted in the reports of a drug firm without the whole context often leads to misunderstanding of the meaning of the original author.

CHEMISTRY OF THE BARBITURATES

The substances known as sodium amytal, nembutal, pernocton, hebaral, sodium soneryl, and sodium evipan all belong to the large new group of barbiturates which modern research has elaborated. The pioneer work in basal anaesthesia by Zerkas of Indianapolis with sodium amytal and by Lundy of the Mayo Clinic with sodium amytal and nembutal (which Lundy originally called enibutal) should be recalled. In 1930 the present writer, together with Dr. Magill, Dr. Apperly, and Dr. Parsons, witnessed some of the work in American and Canadian clinics, and subsequently the possibilities of the various methods which are available in this interesting branch of anaesthetics have been explored by many anaesthetists in this country.

The chemistry of the barbiturates is important but somewhat obscure. For help in the compilation of the brief but by no means complete account which follows I have to thank Dr. Nierenstein of Bristol and Mr. Garfield Thomas of the Birmingham General Hospital.

About thirty years ago it was pointed out by Nebenthan that if one prepared an isomer of urea, a drug could be prepared which produced hypnotic qualities. Now urea NH_2CO has the linkage $-\text{NH}-\text{CO}$, which can be tautomerized to $-\text{N}=\text{C}(\text{OH})$. The position, however, becomes more complicated in the case of barbituric acid. Here the system $-\text{NH}-\text{CO}-\text{CH}_2-$ may tautomerize to $-\text{N}=\text{C}(\text{OH})-\text{CH}_2-$, and thus produce a substance possessing hypnotic properties, or $-\text{NH}-\text{C}(\text{OH})=\text{CH}-$ may be formed, which would thus exclude the production of an hypnotic. This actually takes place in barbituric acid, which has no hypnotic properties. This tautomeric form $-\text{N}=\text{C}(\text{OH})-$ is termed "the Nebenthan factor." In order to render the new linkage a stable compound, various groups such as ethyl groups replace the mobile hydrogen atoms. This opened up a new era for the

* Delivered to the Midland Medical Society, January 10th, 1934.

drug manufacturers, and a variety of hypnotic drugs were prepared with names which differed according to the nature of the immobile radicles—veronal, allonal, neonal, lumnal, etc.

Now in more recent years we have become aware that, for some reason, substances which contain an asymmetric carbon atom (and which are optically active), possess very powerful physiological effects in the body (for example, the carbohydrates, the proteins, the alkaloids, and adrenaline). The effort was then made to prepare a derivative of the barbiturates which contained both the Nebenthou factor and, in the affixed radicles, an asymmetric carbon atom. These substances, of which nembutal (sodium ethyl (1-methylbutyl) barbiturate) is a well-known example, are employed in the form of the sodium salts which are soluble in water, with the result that they can be readily absorbed from the intestine. The presence of an asymmetric carbon atom suggests the possibility that the strength of specimens may vary according to the proportions of dextrorotatory and laevorotatory moieties which are present. Mr. Garfield Thomas, however, upon examining a few specimens of nembutal, has not found the optical activity to vary greatly. This point may be worthy of further attention.

In addition to the influence of (1) the Nebenthou factor and (2) the asymmetric carbon atom, the hypnotic power of the barbiturates also varies considerably with (3) the complexity and composition of the side-chains, and other affixed radicles.

THE NEWER COMPOUNDS AND THEIR EFFECTS

The duration of their effects differs, and the differences depend partly on the rate of excretion of the unaltered drug and partly on the rate of destruction of the drug in the body. Barbituric acid itself is inert, and therefore the drugs are rendered inert by the oxidation of their side-chains, so that the drugs with the least stable side-chains produce the shortest actions. Lumnal is oxidized but slowly, it is slow-acting, and it is of great value in epilepsy. Sodium amylal and nembutal are short-acting. Sodium evipan is oxidized the most rapidly of all.

The drugs are removed from the body by oxidation and detoxication (principally in the liver) and elimination through the kidneys. In the case of sodium evipan, apparently, these processes occur with such rapidity that the effects of an overdose soon pass off provided that respiration and circulation can be prevented from failing completely.

A number of these compounds have been prepared, and it may perhaps be remarked that the researches into their action in animals and in human beings have proved to be more fruitful in those countries which possess ample opportunities for animal experimentation, such as Germany and America.

The best known of the newer barbiturates are: sodium iso-amyl-ethyl barbiturate (sodium amylal), sodium ethyl (1-methylbutyl) barbiturate (nembutal), butyl-b-bromallyl barbituric acid (pernocton), and sodium *n*-methyl-C-cyclophenyl-methyl barbiturate (sodium evipan). Pernocton possesses a bromine atom, and it is therefore

more than a simple barbiturate. Sodium soneryl, hebaral, and somnifene are members of the same group which are employed by many workers. They do not all possess an asymmetric carbon atom.

Lundy has pointed out that for practical purposes he divides the effects into three stages: Stage I (*hypnosis*): The patient can be roused to speak and even to voice his disapproval if pinched, but subsequently he has little or no memory of the incident. Stage II (*inebriation*): He moves when the skin is stimulated, and may be restless, but he shows no signs of consciousness. Local anaesthesia is not in all cases aided by this stage, because the restlessness may cause an operative procedure to be well-nigh impossible. Stage III (*anaesthesia*): There is no response to painful stimuli, but often in this stage respiratory depression, a fall in blood pressure, and a tendency for the tongue to fall back are observed. Shock, and pulmonary oedema leading to bronchopneumonia, may result from a particularly large dose of the barbiturate.

One may sum up the situation by saying that the first stage—hypnosis—is generally achieved with administration by the mouth; inebriation—that is to say, complete unconsciousness—with administration by intravenous injection; the third stage—narcosis—is not generally regarded as desirable in the case of sodium amylal, nembutal, and pernocton, but the new drug known as sodium evipan is said to be relatively safe as a true narcotic. Thus, in dogs, the minimal dose of sodium evipan is said to be more than five times the minimal narcotic dose.

ADMINISTRATION

In administration of the barbiturates the oral and intravenous routes are generally found to be the more useful. Intramuscular injection and instillation of a barbiturate solution into the large bowel have also been employed. I have not had much experience of the intramuscular route. In my hands the onset of hypnosis is delayed, a relatively large dose is required to obtain sleep, and one is chary of employing the method because one does not dare to give an adequate dose from the fear that when at last the whole of the solution has entered the circulation and the full effects have developed, the patient may suffer from an overdose. I have not employed the rectal method in many cases. It is not particularly convenient, and the correct dosage is not easily determined.

Avertin (tribromomethyl alcohol, $\text{CBr}_3\text{CH}_2\text{OH}$) is well known. I would remind you that the solid avertin is supplied in solution in amylene hydrate (1 gram in 1 c.cm. of solution), that it is sparingly soluble in water, so that the watery solution which is instilled into the patient is of large bulk, and that the rectal route is almost universally employed. When given intravenously avertin is detoxicated by the liver so rapidly that consciousness returns only a few minutes after the administration has been completed. The rectal method offers slow, steady absorption, and when 0.1 gram of avertin has been given for each kilogram of body weight, the patient remains unconscious usually for a period of two to three hours. Shipway, in a personal communication based upon more than 12,000 cases, expresses his entire satisfaction with rectal avertin. Wesley Bourne of Montreal has administered avertin to one patient on twenty-two occasions within a period of ten weeks without injury to the liver or any other untoward effect.

A CONTRAST WITH GASEOUS ANAESTHETICS

Perhaps the most noteworthy point to be emphasized is the striking contrast between the gaseous anaesthetics and these solid narcotics in absorption, in action, and

can, however, be surmised from the solubility of the substance. If a quick effect is desired a barbiturate containing sodium should be used.

Hang-over and Cumulation

The questions of hang-over and cumulation depend upon the completeness with which the drug is dealt with by excretion or detoxication over periods of eight and twenty-four hours respectively. They are best determined by therapeutic trial, but the laboratory data are of interest. Barbiturates meet with various fates after ingestion. Some are re-excreted, others are broken down, and others disappear mysteriously. Frethwurst, Halberkann, and Reiche⁶ could recover 75 per cent. of a given dose of barbitone from the urine, 65 per cent. of pernocton, only 30 per cent. of dial, between 10 and 40 per cent. of luminal, and no amyltal or neonal at all. Evipan is said to be metabolized completely in a few hours. Clearly urine analysis alone does not yield any reliable index of the probability of hang-over. Cumulation is more easily determined, especially if the drug is recoverable in part from the urine. Barbitone is known to be a serious offender, and the following analyses⁷ furnish the chemical explanation of the defect: only 8 per cent. appears in the urine in the first twelve hours; 20 per cent. in the first twenty-four; 36 per cent. in the first forty-eight; and traces can be found for as long as nine days after a single dose.

A number of other important points are only decided after the drug has come into wide use and experience has accumulated. Toxic effects may arise, due not so much to the cumulation of the drug in the tissues as to the summation of its effect on the tissues. Mental impairment and the motor paralysis following luminal are examples of this kind of trouble. The range of possible idiosyncrasies and the degree to which the patient is exposed to the risks of addiction are only discernible after the drug has been in use for years.

TABLE V.—Some Hypnotic Mixtures

Alepsal	= Phenobarbital, belladonna, and caffeine
Bental	= Barbitone, valerian, and hyoscyamus
Belladenal	= Phenobarbital and the alkaloids of belladonna
Bromidia	= Chloral bromide and hyoscyamus
Bromovalerianate	= Chloral bromides and valerian
Brosedan	= Bromide and yeast
Indonal	= Barbitone and cannabis indica
Neurinase	= Soluble barbitone and valerian
Theogardenal	= Butobarbital and theobromine
Veronidia	= Soluble barbitone and passion flower

PRACTICAL SUGGESTIONS

1. The rejection for general use of any proprietary preparation which is merely a mixture of old familiar friends. It may be appropriate when circumstances are exceptional.

2. The rejection of any proprietary preparation exploiting the pain-relieving properties of amidopyrine and other coal-tar analgesics. These parent substances can be prescribed from the B.P., with the addition, if desirable, of the hypnotic of individual choice. Similar rules could be formulated on a rational basis in all branches of this subject of the proprietaries. If universally adopted they would spare the memory a great and daily increasing burden.

BASAL ANAESTHETICS AND ALLIED SUBSTANCES

THEIR USE AND MISUSE*

BY

H. W. FEATHERSTONE, M.A., M.D.,

HONORARY ANAESTHETIST, GENERAL, CHILDREN'S, AND MATERNITY HOSPITALS, BIRMINGHAM; LECTURER ON ANAESTHETICS IN THE UNIVERSITY OF BIRMINGHAM

The group of anaesthetic agents to which a great deal of attention has been drawn in the last few years are solids which are administered to the patient in solution in water. They provide a contrast to the well-known anaesthetic gases which are absorbed through the lungs. In this paper the attempt is made to discuss this group of non-inhalational narcotics, many of which, in view of the incomplete nature of the anaesthesia they produce when given in safe doses, have been termed "basal anaesthetics."

Although a great deal has been written on the subject by manufacturers, anaesthetists in this country have not yet offered discriminating criticism to any large extent. The medical profession and the public owe much of the progress of therapeutics in modern times to the research departments of the great drug and chemical manufacturers; but it is very necessary that judgement on the relative values of the products which these important firms offer should be dispassionate in order that, in a particular condition, the most suitable drug may be selected. To read a short excerpt quoted in the reports of a drug firm without the whole context often leads to misunderstanding of the meaning of the original author.

CHEMISTRY OF THE BARBITURATES

The substances known as sodium amytal, nembutal, pernocton, hebaral, sodium soneryl, and sodium evipan all belong to the large new group of barbiturates which modern research has elaborated. The pioneer work in basal anaesthesia by Zerkas of Indianapolis with sodium amytal and by Lundy of the Mayo Clinic with sodium amytal and nembutal (which Lundy originally called embutal) should be recalled. In 1930 the present writer, together with Dr. Magill, Dr. Apperly, and Dr. Parsons, witnessed some of the work in American and Canadian clinics, and subsequently the possibilities of the various methods which are available in this interesting branch of anaesthetics have been explored by many anaesthetists in this country.

The chemistry of the barbiturates is important but somewhat obscure. For help in the compilation of the brief but by no means complete account which follows I have to thank Dr. Nierenstein of Bristol and Mr. Garfield Thomas of the Birmingham General Hospital.

About thirty years ago it was pointed out by Nebenthan that if one prepared an isomer of urea a drug could be prepared which produced hypnotic qualities. Now urea $\text{NH}_2\text{—CO—NH}_2$ has the linkage —NH—CO— , which can be tautomerized to —N=C(OH)— . The position, however, becomes more complicated in the case of barbituric acid. Here the system $\text{—NH—CO—CH}_2\text{—}$ may tautomerize to $\text{—N=C(OH)—CH}_2\text{—}$, and thus produce a substance possessing hypnotic properties, or —NH—C(OH)=CH— may be formed, which would thus exclude the production of an hypnotic. This actually takes place in barbituric acid, which has no hypnotic properties. This tautomeric form —N=C(OH)— is termed "the Nebenthan factor." In order to render the new linkage a stable compound, various groups such as ethyl groups replace the mobile hydrogen atoms. This opened up a new era for the

g manufacturers, and a variety of hypnotic drugs are prepared with names which differed according to the nature of the immobile radicals—veronal, allonal, neonal, ninal, etc.

Now in more recent years we have become aware that, for some reason, substances which contain an asymmetric carbon atom (and which are optically active), possess very powerful physiological effects in the body (for example, the carbohydrates, the proteins, the alkaloids, and adrenaline). The effort was then made to prepare a derivative of the barbiturates, which contained both the Nebenthan factor and, in the affixed radicals, an asymmetric carbon atom. These substances, of which nembutal (sodium ethyl (1-methylbutyl) barbiturate) is a well-known example, are employed in the form of the sodium salts which are soluble in water, with the result that they can be readily absorbed from the intestine. The presence of an asymmetric carbon atom suggests the possibility that the strength of specimens may vary according to the proportions of dextrorotatory and levorotatory moieties which are present. Mr. Gifford Thomas, however, upon examining a few specimens of nembutal, has not found the optical activity to vary greatly. This point may be worthy of further attention.

In addition to the influence of (1) the Nebenthan factor and (2) the asymmetric carbon atom, the hypnotic power of the barbiturates also varies considerably with (3) the complexity and composition of the side-chains, and other affixed radicals.

THE NEWER COMPOUNDS AND THEIR EFFECTS

The duration of their effects differs, and the differences depend partly on the rate of excretion of the unaltered drug and partly on the rate of destruction of the drug in the body. Barbituric acid itself is inert, and therefore the drugs are rendered inert by the oxidation of their side-chains, so that the drugs with the least stable side chains produce the shortest actions. Luminal is oxidized but slowly, it is slow-acting, and it is of great value in epilepsy. Sodium amytal and nembutal are short-acting. Sodium evipan is oxidized the most rapidly of all.

The drugs are removed from the body by oxidation and detoxication (principally in the liver) and elimination through the kidneys. In the case of sodium evipan, apparently, these processes occur with such rapidity that the effects of an overdose soon pass off provided that respiration and circulation can be prevented from failing completely.

A number of these compounds have been prepared, and it may perhaps be remarked that the researches into their action in animals and in human beings have proved to be more fruitful in those countries which possess ample opportunities for animal experimentation, such as Germany and America.

The best known of the newer barbiturates are: sodium (α-amy-ethyl) barbiturate (sodium amytal), sodium ethyl (1-methylbutyl) barbiturate (nembutal), butyl-b-hromallyl barbituric acid (pernocton), and sodium *n*-methyl-C-C-cyclophenyl-methyl barbiturate (sodium evipan). Pernocton possesses a bromine atom, and it is therefore

more than a simple barbiturate. Sodium soneryl, hebaral, and somnilene are members of the same group which are employed by many workers. They do not all possess an asymmetric carbon atom.

Lundy has pointed out that for practical purposes he divides the effects into three stages: Stage I (*hypnosis*): The patient can be roused to speak and even to voice his disapproval if pinched, but subsequently he has little or no memory of the incident. Stage II (*mebriation*): He moves when the skin is stimulated, and may be restless, but he shows no signs of consciousness. Local anaesthesia is not in all cases aided by this stage, because the restlessness may cause an operative procedure to be well-nigh impossible. Stage III (*anaesthesia*): There is no response to painful stimuli, but often in this stage respiratory depression, a fall in blood pressure, and a tendency for the tongue to fall back are observed. Shock, and pulmonary oedema leading to bronchopneumonia, may result from a particularly large dose of the barbiturate.

One may sum up the situation by saying that the first stage—hypnosis—is generally achieved with administration by the mouth; mebriation—that is to say, complete unconsciousness—with administration by intravenous injection; the third stage—narcosis—is not generally regarded as desirable in the case of sodium amytal, nembutal, and pemocton, but the new drug known as sodium evipan is said to be relatively safe as a true narcotic. Thus, in dogs, the minimal dose of sodium evipan is said to be more than five times the minimal narcotic dose.

ADMINISTRATION

In administration of the barbiturates the oral and intravenous routes are generally found to be the more useful. Intramuscular injection and instillation of a barbiturate solution into the large bowel have also been employed. I have not had much experience of the intramuscular route. In my hands the onset of hypnosis is delayed, a relatively large dose is required to obtain sleep, and one is chary of employing the method because one does not dare to give an adequate dose from the fear that when at last the whole of the solution has entered the circulation and the full effects have developed, the patient may suffer from an overdose. I have not employed the rectal method in many cases. It is not particularly convenient, and the correct dosage is not easily determined.

Avertin (tribromethyl alcohol, $\text{CBr}_3\text{CH}_2\text{OH}$) is well known. I would remind you that the solid avertin is supplied in solution in amylene hydrate (1 gram in 1 c.cm. of solution), that it is sparingly soluble in water, so that the watery solution which is instilled into the patient is of large bulk, and that the rectal route is almost universally employed. When given intravenously avertin is detoxicated by the liver so rapidly that consciousness returns only a few minutes after the administration has been completed. The rectal method offers slow, steady absorption, and when 0.1 gram of avertin has been given for each kilogram of body weight, the patient remains unconscious usually for a period of two to three hours. Shipway, in a personal communication based upon more than 12,000 cases, expresses his entire satisfaction with rectal avertin. Wesley Bourne of Montreal has administered avertin to one patient on twenty-two occasions within a period of ten weeks without injury to the liver or any other untoward effect.

A CONTRAST WITH GASEOUS ANAESTHETICS

Perhaps the most noteworthy point to be emphasized is the striking contrast between the gaseous anaesthetics and these solid narcotics in absorption, in action, and

can, however, be surmised from the solubility of the substance. If a quick effect is desired a barbiturate containing sodium should be used.

Hang-over and Cumulation

The questions of hang-over and cumulation depend upon the completeness with which the drug is dealt with by excretion or detoxication over periods of eight and twenty-four hours respectively. They are best determined by therapeutic trial, but the laboratory data are of interest. Barbiturates meet with various fates after ingestion. Some are re-excreted, others are broken down, and others disappear mysteriously. Frethwurst, Halberkann, and Reiche⁶ could recover 75 per cent. of a given dose of barbitone from the urine, 65 per cent. of pernocton, only 30 per cent. of dial, between 10 and 40 per cent. of luminal, and no amytal or neonal at all. Evipan is said to be metabolized completely in a few hours. Clearly urine analysis alone does not yield any reliable index of the probability of hang-over. Cumulation is more easily determined, especially if the drug is recoverable in part from the urine. Barbitone is known to be a serious offender, and the following analyses⁷ furnish the chemical explanation of the defect: only 8 per cent. appears in the urine in the first twelve hours; 20 per cent. in the first twenty-four; 36 per cent. in the first forty-eight; and traces can be found for as long as nine days after a single dose.

A number of other important points are only decided after the drug has come into wide use and experience has accumulated. Toxic effects may arise, due not so much to the cumulation of the drug in the tissues as to the summation of its effect on the tissues. Mental impairment and the motor paralysis following luminal are examples of this kind of trouble. The range of possible idiosyncrasies and the degree to which the patient is exposed to the risks of addiction are only discernible after the drug has been in use for years.

BASAL ANAESTHETICS AND ALLIED SUBSTANCES

THEIR USE AND MISUSE*

BY

H. W. FEATHERSTONE, M.A., M.D.,

HONORARY ANAESTHETIST, GENERAL, CHILDREN'S, AND MATERNITY HOSPITALS, BIRMINGHAM; LECTURER ON ANAESTHETICS IN THE UNIVERSITY OF BIRMINGHAM

The group of anaesthetic agents to which a great deal of attention has been drawn in the last few years are solids which are administered to the patient in solution in water. They provide a contrast to the well-known anaesthetic gases which are absorbed through the lungs. In this paper the attempt is made to discuss this group of non-inhalational narcotics, many of which, in view of the incomplete nature of the anaesthesia they produce when given in safe doses, have been termed "basal anaesthetics."

Although a great deal has been written on the subject by manufacturers, anaesthetists in this country have not yet offered discriminating criticism to any large extent. The medical profession and the public owe much of the progress of therapeutics in modern times to the research departments of the great drug and chemical manufacturers; but it is very necessary that judgement on the relative values of the products which these important firms offer should be dispassionate in order that, in a particular condition, the most suitable drug may be selected. To read a short excerpt quoted in the reports of a drug firm without the whole context often leads to misunderstanding of the meaning of the original author.

CHEMISTRY OF THE BARBITURATES

The substances known as sodium amytal, nembutal, pernocton, hebaral, sodium soueryl, and sodium evipan all belong to the large new group of barbiturates which modern research has elaborated. The pioneer work in basal anaesthesia by Zerfas of Indianapolis with sodium amytal and by Lundy of the Mayo Clinic with sodium amytal and nembutal (which Lundy originally called embutal) should be recalled. In 1930 the present writer, together with Dr. Magill, Dr. Apperly, and Dr. Parsons, witnessed some of the work in American and Canadian clinics, and subsequently the possibilities of the various methods which are available in this interesting branch of anaesthetics have been explored by many anaesthetists in this country.

The chemistry of the barbiturates is important but somewhat obscure. For help in the compilation of the brief but by no means complete account which follows I have to thank Dr. Nierenstein of Bristol and Mr. Garfield Thomas of the Birmingham General Hospital.

About thirty years ago it was pointed out by Nebenthan that if one prepared an isomer of urea a drug could be prepared which produced hypnotic qualities. Now urea $\text{NH}_2\text{—CO—NH}_2$ has the linkage —NH—CO— , which can be tautomerized to —N=C(OH)— . The position, however, becomes more complicated in the case of barbituric acid. Here the system $\text{—NH—CO—CH}_2\text{—}$ may tautomerize to $\text{—N=C(OH)—CH}_2\text{—}$, and thus produce a substance possessing hypnotic properties, or —NH—C(OH)=CH— may be formed, which would thus exclude the production of an hypnotic. This actually takes place in barbituric acid, which has no hypnotic properties. This tautomeric form —N=C(OH)— is termed "the Nebenthan factor." In order to render the new linkage a stable compound, various groups such as ethyl groups replace the mobile hydrogen atoms. This opened up a new era for the

drug manufacturers, and a variety of hypnotic drugs were prepared with names which differed according to the nature of the immobile radicles—veronal, allonal, neonal, luminal, etc.

Now in more recent years we have become aware that, for some reason, substances which contain an asymmetric carbon atom (and which are optically active), possess very powerful physiological effects in the body (for example, the carbohydrates, the proteins, the alkaloids, and adrenaline). The effort was then made to prepare a derivative of the barbiturates which contained both the Nebenthou factor and, in the affixed radicles, an asymmetric carbon atom. These substances, of which nembital (sodium ethyl (1-methylbutyl) barbiturate) is a well-known example, are employed in the form of the sodium salts which are soluble in water, with the result that they can be readily absorbed from the intestine. The presence of an asymmetric carbon atom suggests the possibility that the strength of specimens may vary according to the proportions of dextrorotatory and laevorotatory moieties which are present. Mr. Garfield Thomas, however, upon examining a few specimens of nembital, has not found the optical activity to vary greatly. This point may be worthy of further attention.

In addition to the influence of (1) the Nebenthou factor and (2) the asymmetric carbon atom, the hypnotic power of the barbiturates also varies considerably with (3) the complexity and composition of the side-chains, and other affixed radicles.

THE NEWER COMPOUNDS AND THEIR EFFECTS

The duration of their effects differs, and the differences depend partly on the rate of excretion of the unaltered drug and partly on the rate of destruction of the drug in the body. Barbituric acid itself is inert, and therefore the drugs are rendered inert by the oxidation of their side-chains, so that the drugs with the least stable side-chains produce the shortest actions. Luminal is oxidized but slowly, it is slow-acting, and it is of great value in epilepsy. Sodium amytal and nembital are short-acting. Sodium evipan is oxidized the most rapidly of all.

The drugs are removed from the body by oxidation and detoxication (principally in the liver) and elimination through the kidneys. In the case of sodium evipan, apparently, these processes occur with such rapidity that the effects of an overdose soon pass off provided that respiration and circulation can be prevented from failing completely.

A number of these compounds have been prepared, and it may perhaps be remarked that the researches into their action in animals and in human beings have proved to be more fruitful in those countries which possess ample opportunities for animal experimentation, such as Germany and America.

The best known of the newer barbiturates are: sodium iso-amyl-ethyl-barbiturate (sodium amytal), sodium ethyl (1-methylbutyl) barbiturate (nembital), butyl-b-bromallyl barbituric acid (pernocton), and sodium *n*-methyl-C-C-cyclophenyl-methyl barbiturate (sodium evipan). Pernocton possesses a bromine atom, and it is therefore

more than a simple barbiturate. Sodium soneryl, hebaral, and somnifene are members of the same group which are employed by many workers. They do not all possess an asymmetric carbon atom.

Lundy has pointed out that for practical purposes he divides the effects into three stages: Stage I (*hypnosis*): The patient can be roused to speak and even to voice his disapproval if pinched, but subsequently he has little or no memory of the incident. Stage II (*inebriation*): He moves when the skin is stimulated, and may be restless, but he shows no signs of consciousness. Local anaesthesia is not in all cases aided by this stage, because the restlessness may cause an operative procedure to be well-nigh impossible. Stage III (*anaesthesia*): There is no response to painful stimuli, but often in this stage respiratory depression, a fall in blood pressure, and a tendency for the tongue to fall back are observed. Shock, and pulmonary oedema leading to broncho-pneumonia, may result from a particularly large dose of the barbiturate.

One may sum up the situation by saying that the first stage—hypnosis—is generally achieved with administration by the mouth; inebriation—that is to say, complete unconsciousness—with administration by intravenous injection; the third stage—narcosis—is not generally regarded as desirable in the case of sodium amytal, nembital, and pernocton, but the new drug known as sodium evipan is said to be relatively safe as a true narcotic. Thus, in dogs, the minimal dose of sodium evipan is said to be more than five times the minimal narcotic dose.

ADMINISTRATION

In administration of the barbiturates the oral and intravenous routes are generally found to be the more useful. Intramuscular injection and instillation of a barbiturate solution into the large bowel have also been employed. I have not had much experience of the intramuscular route. In my hands the onset of hypnosis is delayed, a relatively large dose is required to obtain sleep, and one is chary of employing the method because one does not dare to give an adequate dose from the fear that when at last the whole of the solution has entered the circulation and the full effects have developed, the patient may suffer from an overdose. I have not employed the rectal method in many cases. It is not particularly convenient, and the correct dosage is not easily determined.

Avertin (tribromomethyl alcohol, $\text{CBr}_3\text{CH}_2\text{OH}$) is well known. I would remind you that the solid avertin is supplied in solution in amylene hydrate (1 gram in 1 c.cm. of solution), that it is sparingly soluble in water, so that the watery solution which is instilled into the patient is of large bulk, and that the rectal route is almost universally employed. When given intravenously avertin is detoxicated by the liver so rapidly that consciousness returns only a few minutes after the administration has been completed. The rectal method offers slow, steady absorption, and when 0.1 gram of avertin has been given for each kilogram of body weight, the patient remains unconscious usually for a period of two to three hours. Shipway, in a personal communication based upon more than 12,000 cases, expresses his entire satisfaction with rectal avertin. Wesley Bourne of Montreal has administered avertin to one patient on twenty-two occasions within a period of ten weeks without injury to the liver or any other untoward effect.

A CONTRAST WITH GASEOUS ANAESTHETICS

Perhaps the most noteworthy point to be emphasized is the striking contrast between the gaseous anaesthetics and these solid narcotics in absorption, in action, and

in excretion. On the one hand, gaseous anaesthetics are absorbed by the lungs, the amount in the body at any particular time can be controlled with remarkable precision (particularly in the case of nitrous oxide, ethylene, acetylene, etc.), and they are excreted by the lungs without detectable alteration in their chemical composition. (It may be that chloroform and ethyl chloride are to some extent destroyed by the liver.) The principal disadvantages of the gaseous group are, first, the dislike some patients have of going through the ordeal of induction, and, secondly, the strain which is thrown upon the pulmonary tissues.

On the other hand, the problems of absorption, action, and elimination of the solid narcotics are much more complicated. Absorption depends upon the method of administration, and although these drugs are greatly appreciated by most patients, the effective dose is difficult to control. The action of the drug so long as its composition is unchanged is probably constant, but the processes of detoxication and elimination begin immediately the drug appears in the circulation.

Therefore the duration and depth of narcosis depends upon the nature of the drug, the dose, the type and temperament of the patient, the state of the heart and circulation, and the efficiency of the liver and of the kidneys. With general anaesthetics most of these problems can be dealt with as anaesthesia proceeds, for the dose is controlled from minute to minute, but all the points should be taken into consideration most carefully beforehand when administering an effective dose of a solid narcotic. After a solid narcotic has been injected, reduction of the effect of the drug is beyond the power of the administrator. Certain measures, however, are very helpful. The circulation and respiration may be improved by inhalations of carbon dioxide and oxygen combined with injections of coramine, and adrenaline or ephedrine. For the pulmonary oedema, which may occur when injecting a large dose of a barbiturate, intravenous injections of hypertonic saline with glucose, together with atropine, are recommended. It is claimed that the effects of avertin may be greatly reduced by the injection of coramine. Some think that avertin is antagonistic to iodothyrene, and that avertin is therefore specially safe in exophthalmic goitre.

THE PATIENT AND PRE-OPERATIVE SEDATIVES

I now propose to review a number of the points which have to be borne in mind if these useful drugs are to be employed to their best advantage, and they will be considered from the point of view of the patient, of the surgeon, and of the anaesthetist. The great demand by patients for the use of basal narcotics is sufficient evidence that, from the patient's point of view, the quiet and comfortable induction of sleep which these drugs offer supplies a long-felt want. Although in particular cases there may be clear reasons for withholding pre-operative sedatives, nevertheless we must accept the fact that these drugs (improved upon, no doubt, as research progresses) must be included in the armamentarium of modern anaesthetists.

We all know that it is comparatively easy with a small dose of anaesthetic to induce and maintain anaesthesia in patients who possess a calm and philosophical outlook, and also in those who are quietened by severe illness and a long period in bed. But the excitable, apprehensive, vigorous individual often requires a large dose of anaesthetic and careful handling. The alcoholic is especially difficult. In these cases the barbiturates are often most helpful and comparatively safe. For alcoholics avertin gives excellent results, and the lungs (which are frequently in a poor condition) are spared the assault of a concentrated vapour.

Oral nembutal does not always answer very well if the patient is excitable, and particularly if he is aware of the nature of the drug which he is swallowing. In such a case the pylorus may be firmly closed, the barbiturate may be retained in the stomach, and the hydrochloric acid of the gastric juice may then react with the sodium of the barbiturate, with the result that the insoluble barbiturate is deposited. It is then absorbed very slowly or not at all. A small dose of omnopon beforehand and darkening of the bedroom will, in such cases, prepare the patient for rapid absorption of the barbiturate.

For the later cases in a long operation list, an early dose of oral nembutal is a kindly help with which to dull apprehension. Attention should be drawn to the value of a dose of nembutal on the night before operation. The rectal injection of avertin is a reliable aid for most patients, but as a routine measure it adds to the responsibilities and to the amount of work entailed for the operating and nursing staff. For patients who require repeated minor operations, and particularly for children, oral nembutal is a great boon. To obtain good results in children the following suggestions may be helpful. (1) The dose of nembutal by the mouth should be small (1 grain or less for a child 4 years old). (2) It is advisable, when possible, to give the sedative at night, when the child is tired. He will then fall asleep in his bed, and general anaesthesia can be induced without waking him. (3) Capsules often are refused, but the powder may be dissolved in a teaspoonful of syrup or in a strong solution of cane sugar in warm water. The extremely bitter taste of the barbiturate is thus masked. (4) If the barbiturate is not effective or if it is vomited, a very small dose of avertin—for example, 0.05 gram per kilogram—may be given by the rectum. These methods enable us to anaesthetize small children repeatedly without their being aware that they have been operated upon at all. Experience has proved their value for such procedures as the setting of fractures, repeated lavage of nasal sinuses, and multiple operations for cellulitis or pyaemia.

In cases following anaesthetics in which a full dose of oral nembutal has been used there is sometimes a long period of partial or complete loss of memory. A powerfully built doctor dropped off to sleep before a double hernia operation as the result of swallowing 6 grains of nembutal. He did not regain complete wide-awake consciousness until two days had elapsed. This was quite satisfactory for him, because he was spared much unpleasantness, but it increased the strain on his attendants.

From the patient's point of view there is the additional advantage that in healthy subjects the frequency of post-anaesthetic vomiting is reduced by employing any basal narcotic. Vomiting, due to liver weakness, intestinal obstruction, or other causes may be increased.

THE SURGEON AND BASAL ANAESTHETICS

From the surgical point of view uniformly good results can be obtained only by employing a suitable drug with appropriate technique. For operations on the stomach barbiturates should be given intravenously, but a fall in blood pressure is often caused, and rectal avertin produces less disturbance. In American clinics intravenous nembutal followed by ethylene-oxygen-ether or gas-oxygen-ether has yielded excellent results. For operations on the appendix and large bowel there are reasons why the rectal administration of drugs should be avoided.

For prolonged surgical operations, where depth of anaesthesia and muscular relaxation is not required, intravenous injection of a barbiturate combined with gas-oxygen is an excellent method. Plastic surgery has proved to be an admirable field for this technique (Magill). Avertin is also good, but the blood loss is rather more than with barbiturates. For cerebral surgery, oral nem-

bital with omnopon, followed by a very little anaesthetic and some oxygen, has yielded very good results. In gynaecological plastic surgery a similar method is recommended, for haemorrhage is thereby reduced (Fairlie). In thyroid surgery the barbiturates have received an extended trial, but I am not enamoured of the method. Certainly for a second operation on a patient who has already lost half her thyroid by the method of stealing it, the variety of routes enables one to put the patient to sleep without her knowledge. But the oral route is not sufficiently powerful for these highly sensitive nervous systems, or at least a good deal of inhalational anaesthesia must be added. Furthermore, the intravenous injection of a barbiturate into a patient whose heart is exhausted from Graves's disease is a highly dangerous procedure. These patients may be almost moribund, and the slight fall in blood pressure occasioned by the injection, together with the small degrees of cyanosis which often accompanies it, may prove fatal. Excellent results usually are obtained with avertin preceded by omnopon and hyoscine, and followed by local anaesthesia, with gas-oxygen if necessary.

Ear and throat surgeons are, I think, divided in their opinions. For simple operations in nervous patients, such as tonsillectomy, the pre-operative sedation with oral nembital may be helpful. But in operations on the upper air passages, the prolonged period of dulled cough reflex, together with restlessness, is apt to lead to trouble during the hours following operation. During septum operations and other procedures under local anaesthesia, absolute quietude is not always obtained, and the operation may be impeded by the restlessness and talkativeness of the patient. I think laryngologists will agree that avertin gives a quiet sleep, more rapid recovery, and less restlessness.

In dental surgery the barbiturates should be used with discretion. If the operation is an extraction in the dental chair, an exceedingly nervous patient may be helped to take gas peacefully when a dose of nembital has been swallowed beforehand, but the dentist must be prepared to keep the patient on a couch for several hours afterwards. For larger procedures such as the extraction of many teeth in a nursing home, the quiet anaesthesia resulting from a combination of general anaesthesia with a barbiturate is very pleasant. But should the tooth sockets bleed after the patient has returned to bed it is often difficult in such cases to make the patient bite on to swabs in order to stanch the haemorrhage. Intravenous sodium evipan, which is detoxicated more rapidly than the other barbiturates, enables the patient to recover consciousness and a completely active cough reflex more rapidly, and it is probable that it will serve a useful purpose both in laryngology and in dentistry.

This drug is receiving a good deal of attention just now. Induction of anaesthesia is quicker, narcosis may be taken to a greater depth with safety, and recovery is rapid. By itself the uses of the drug are, I think, somewhat limited. It is not usual for full anaesthesia to last for more than a quarter of an hour. Therefore, if the drug be given while the patient is in bed, there is not much time in which to take him to the theatre, to prepare him for the operation, and to perform it. In most cases it is necessary to continue with an inhalational anaesthetic. For tooth extractions, for the setting of fractures, for painful dressings, and for brief gynaecological procedures, the drug seems to be valuable, but I do not find that the indications for its use are by any means numerous. If one dose only is to be given, without any other anaesthetic, it is usually necessary that the patient should be fully prepared on the operating table before the injection is begun. Surely less pleasant than a general anaesthetic! In my experience there is a period of an hour or more following the stage of

narcosis when the patient is drowsy and sometimes incoherent. I find that post-operative restlessness is not so marked with sodium evipan as with nembital.

In obstetrics the barbiturates have received a considerable test. My own experiences may be summarized as follows. Usually a full dose of sodium amytal or of nembital injected intravenously just before full dilatation will produce painless labour. It does not affect the frequency of contractions; usually it appears relatively to increase the expulsive force, and the drug does not lead to any embarrassment of the child. The placenta is born speedily, and post-partum haemorrhage, in my experience, is reduced. This full dose should be given very slowly, otherwise the fall in blood pressure will very properly deter one from giving the full dose which was intended, with the result that full analgesia would not be obtained. It is noteworthy that when the regular contractions of labour have set in, they continue with the same rhythm both during and after the injection of the drug.

When the head is on the perineum progress is not delayed so much as in ordinary labour, and there is the danger that the child may be shot out precipitately, with a severe tear of the perineum as the result. At the time of delivery some patients wriggle about so much that it is not an easy matter to control them and to deliver the head quietly and steadily. The administration of gas-oxygen gives valuable aid at this time, but in a confinement under the influence of a barbiturate the presence of two trained attendants is essential. This uncontrolled restlessness is present in most cases delivered after the oral administration of nembital, while, furthermore, with oral nembital, analgesia is usually not complete. Avertin has given excellent results, but it is, I think, true to say that sometimes the rectal injection of avertin solution is returned, labour tends to be delayed, and the child's respiration may be depressed.

In Caesarean section performed under spinal anaesthesia, nembital by the oral route is a useful sedative. In these cases the fear of depression of the child's respiratory centre precludes us from the use of morphine; but nembital soothes the mother, and it enables the child to be delivered in a vigorous state. It is true that sometimes the child may be rather sleepy, but respiration is easily aroused. Intravenous nembital should be avoided, for the fall in blood pressure induced by the combination of intravenous barbiturate and spinal anaesthesia may be of an alarming degree—as some of us know from experience.

In general medicine nembital and its allied compounds have proved to be helpful. In a case of strychnine poisoning the convulsions were controlled, death was averted until the effects of the drug had worn off, and recovery ensued. It is claimed that strychnine may be employed in barbiturate poisoning, and successful cases are cited. As much as 1/6 grain has been injected hypodermically every six hours. Several cases of tetanus in my own experience have been controlled by intravenous nembital: at least two with a successful cure. Status epilepticus offers a field for the more vigorous barbiturates. For cardiac insomnia the sound sleep promoted by nembital has afforded substantial improvement to the heart. Delirium tremens, mania from various causes, and persistent hiccup are examples of conditions which have benefited greatly from the use of basal narcotics.

We may now consider certain conditions in which the administration of barbiturates is fraught with increased risk for the patient. Sir William Willcox on many occasions has emphasized the risk of pneumonia in those individuals who have received a large dose of a barbiturate. Therefore in the presence of inflammation of the lungs, in operations for empyema, and even in

catarrhal conditions of the bronchi and upper air passages barbiturates should be withheld. In my experience avertin does not involve so great a risk, and if other conditions warrant the use of avertin, the inhalation of a gaseous anaesthetic is reduced in amount and, indeed, may be avoided if local anaesthesia is effective.

When the efficiency of the liver or the kidneys is affected by toxic blood conditions, by local inflammation of those organs, or by other diseases, such as eclampsia or cirrhosis, the fear of further damage to them, together with coma as the result of retarded detoxication and excretion of barbiturates or avertin, will be a sound reason for withholding the drug. It has been remarked by gynaecologists that upon opening the abdomen of patients who have received nembutal the bladder appears to be rather more full than usual. It seems reasonable to think that a certain amount of diuresis is caused by these drugs. In prostatectomy, when the fear of renal insufficiency is particularly acute, a barbiturate would seem to be an unnecessary load.

I have on several occasions given nembutal or avertin with gas and oxygen to patients with diabetes of mild degree. The results have been uneventful, but avertin appears to be preferable in such conditions. Should coma follow the giving of a barbiturate to a diabetic, I should perform lumbar puncture as Purves-Stewart and Wilcox have recommended. These authorities state that in coma caused by a barbiturate the drug can be detected in the cerebro-spinal fluid, and that removal of a quantity of the fluid by lumbar or cisternal puncture always produces at least temporary improvement.

The state of the heart is of importance. In the presence of heart disease, if signs of active toxæmia are absent, the use of avertin with gas and plenty of oxygen is a most valuable measure. In heart disease associated with severe toxic goitre I am quite sure that the intravenous injection of nembutal is dangerous. It may be that the fall in blood pressure which often accompanies this method is the factor which reacts indirectly on the heart, or the problem may be a complicated one concerned with the poor condition of the liver, kidneys, and so forth, but the practical point remains that a toxic heart should not receive an intravenous barbiturate. Even oral nembutal may cause pallor and a lowered blood pressure in apparently normal people. Reference has already been made to the risks of administering an intravenous barbiturate and then injecting a spinal anaesthetic; for the blood pressure may drop to an alarming extent.

There are local conditions of the stomach or bowel, such as inflammation or perforation, which should preclude the introduction of a narcotic solution into the diseased viscus. Some of the conditions such as gastritis, gastric ulcer, perforation, and colitis have already been referred to, and there does seem to be some risk in giving rectal avertin in cases of appendicitis or diverticulitis, particularly if perforation is feared.

It is perhaps well to emphasize the need for making certain that the patient is absolutely ready for operation before the administration of a basal anaesthetic is begun. The operator may desire to make a further examination or to speak to the patient after he has been brought to the anaesthetic room. During the recovery period from anaesthetics in which barbiturates and avertin have been employed, patients often become exceedingly restless. The restlessness is less marked following avertin or sodium evipan. Such restlessness definitely increases the possibility of post-operative recurrent haemorrhage. Very small doses of morphine or omnopon (repeated if necessary) usually control the restlessness. The administration of oxygen is sometimes helpful.

Although basal anaesthetics are a boon to patients, I am not sure that nurses find them convenient. The

preparations beforehand are more complicated than in routine anaesthesia, but the principal disadvantage from the nursing point of view lies in the recovery period. The respiration may be depressed, the tongue may fall back, and the patient may be restless. These conditions usually require that a competent nurse shall sit by the patient for an hour or more after he has returned to the ward. Furthermore, as I have already mentioned, the after-effects of barbiturates may be prolonged, and a relatively small dose may confuse the patient's mind for many hours. This confusion often persists longer than the onlookers realize, so that nurses must be informed of every patient who has received a barbiturate. In the case of avertin a small degree of respiratory depression and trouble with the tongue is not uncommon, but prolonged unconsciousness, amnesia, or confusion is rare.

THE ANAESTHETIST AND BASAL ANAESTHETICS

I have left the anaesthetist's point of view to the last. It is always advisable that an anaesthetist should see a patient on the day before operation, but if a basal anaesthetic is to be given, by the mouth or by the rectum, the preliminary visit is essential. Even with intravenous methods time should be given for a very full consideration of all aspects of the case before the drug is administered.

I have already referred to many of the considerations which must be borne in mind in selecting the particular drug. Sodium amytal has a greater duration than nembutal; it is said that the post-anaesthetic restlessness also is greater, but I am not sure. I have found that pernorton (which is given by the intravenous route) is not so powerful as the two I have just mentioned. Sodium soneryl and hebaral I believe are relatively weak when given in safe doses. Sodium evipan is dramatically effective, but the full ordinary dose of 1 gram does not secure a prolonged effect in every case. The degree of muscular relaxation varies. Jarman, who has carried out extensive clinical investigations, precedes the intravenous injection of sodium evipan with a hypodermic injection of omnopon-scopolamine. In some cases, as the effects of the first injection are wearing off, he administers a second. He has used sodium evipan alone successfully in many cases of appendicectomy. On one occasion he gave four injections of sodium evipan for an operation which lasted nearly two hours, and no other anaesthetic was required.

Dosage.—This is a matter of very great difficulty, and I have already indicated the need to take into consideration the type of the operation and the personal equation of the patient, but the most useful aid is the patient's weight. In the case of avertin a dose of 0.1 gram of the drug for each kilogram of body weight yields fairly uniform results. It is claimed by some anaesthetists that 0.12 gram per kilogram will yield complete anaesthesia in 60 per cent. of cases, but I prefer to stick to the smaller dose of 0.1 gram. When employing intravenous methods greater precision may be attained. It appears to me that usually, at the end of the injection, the anaesthesia begins to lighten almost immediately, but the fall in blood pressure continues for some minutes before it rises once more.

To sum up: (1) it does not seem wise to give a basal narcotic unless the patient has been examined carefully beforehand; (2) the oral route for the barbiturates is convenient, but it may be ineffective or, on the other hand, the effects may be too prolonged; (3) the intravenous route is not always safe; (4) avertin seems to be less convenient but perhaps more reliable: the dose is assessed with greater accuracy and the liver appears to be able to detoxicate the simple molecule of avertin rapidly.

A WARNING REGARDING BASAL NARCOTICS

BY

R. J. McNEILL LOVE, M.S., F.R.C.S.

SURGEON, ROYAL NORTHERN HOSPITAL, ETC.

The widespread use of narcotics in pre-operative medication has certainly relieved the dread and anxiety associated with surgical procedures, especially in sensitive or imaginative patients, but it should be emphasized that these drugs are not entirely free from danger. I append notes of two cases which have occurred in my practice during the past six months, in both of which narcotics were indubitably a contributory cause of death. It must be admitted that other sedatives were administered, and it would appear to be extremely unwise to administer morphine or omnopon in conjunction with basal narcotics.

Patients exhibit an idiosyncrasy to most drugs, and perhaps especially to narcotics. Although pre-operative medication gives excellent results in the majority of cases, yet occasionally an alarming period of unconsciousness results, or even a fatality. It is possible that for various reasons little is heard about these unpleasant results, and therefore basal narcotics are apt to be administered indiscriminately. It is now my practice to administer avertin only in amounts corresponding to two-thirds of the official dose, and supplement its effect with gas and oxygen as necessary. I believe this dose to be comparatively safe, and I find that it is sufficient to render the patient amnesic.

CASE I

The patient, a woman aged 29, had suffered from the typical manifestations of exophthalmic goitre for about a year, and had previously had a course of medical treatment for five months, but after temporary improvement the condition relapsed. On admission to hospital her pulse rate was 132, but this quieted to 96 after treatment in bed and Lugol's iodine. The thyroid gland was moderately enlarged, exophthalmos was present, and there was a systolic murmur. On the morning of the operation $\frac{1}{4}$ grain morphine and $\frac{1}{100}$ grain hyoscine were given hypodermically, followed by 4.4 c.c.m. of avertin per rectum, which is the recognized dose for a patient weighing 7 st. Half an hour after the administration of the avertin the neck was infiltrated with 1 per cent. novocain and a partial thyroidectomy performed. The bulk of both lobes and the isthmus were removed; the operation presented no difficulty, and was completed in about forty-five minutes. Towards the end of the operation signs of respiratory failure became evident, as evinced by cyanosis and slow, shallow respirations. Oxygen inhalation caused a temporary improvement. The operation was rapidly completed, and a pint of glucose and saline, with 30 minims of Lugol's iodine, was administered per rectum. Two hours after operation the temperature was 103°, the pulse 146, and respirations 12 per minute. There was no external bleeding and no signs of extravasation in the neck. Oxygen inhalation was continued, cardiac stimulants were administered, but the pulse rate gradually increased until it became imperceptible. The patient died five hours after the operation was completed without regaining consciousness.

Death in this case appears to have been due to respiratory failure following the administration of avertin, as the pre-operative condition of the patient was highly satisfactory and the operation presented no difficulty.

CASE II

The patient, a woman aged 38, was operated on in June, 1931, for cyst of breast and a femoral hernia. The usual dose of avertin was given, with excellent results. In June, 1932, when in India, she developed an appendix abscess; this was drained on three occasions, and a vesico-vaginal fistula resulted. There was prolonged suppuration, and she returned to England; in June, 1933, the portion of the appendix which was still attached to the caecum was removed. She was given intravenous nembutal with gas, oxygen, and ether, and recovered consciousness in a normal manner two hours after the operation. As the fistula still persisted, with recrudescence of pelvic infection, it was decided that a laparotomy

should be performed and the fistula closed from above. The operation was arranged for 8.15 a.m. on November 20th, and was performed by one of the leading gynaecologists in London. The patient requested that she should again be given nembutal, and on the previous evening $1\frac{1}{2}$ grains (one capsule) of the drug were given orally. At 7.45 a.m. the following day the patient was wide awake. She was given 3 grains of nembutal by the mouth, and $\frac{1}{6}$ grain morphine and $\frac{1}{100}$ grain of atropine hypodermically.

The operation, as was expected, proved to be difficult and tedious. The pelvic organs were buried in a mass of adhesions, but the fistula was competently closed, and an infective blood cyst of the right ovary, to which was attached the remains of the tip of the appendix, was removed. The operation lasted just over two hours, during which time open ether was administered. At the end of the operation the pulse rate was 130, but the general condition was satisfactory. At 12.45 p.m. the patient, though still comatose, became somewhat restless, and was given $\frac{1}{3}$ grain omnopon hypodermically. At 3 p.m. the pulse became thready, and a blood transfusion of 400 c.c.m. was given, followed by one pint of saline and glucose. The condition improved temporarily, but at 6.30 p.m. the pulse rate rose to 156, and more saline and glucose was administered. Throughout the night the respirations gradually became more rapid, and the pulse rate varied between 140 and 160. Further infusions of saline and glucose were given, but at 9 a.m. the following day deep unconsciousness still persisted, although corneal reflexes were brisk. As the continued unconsciousness gave rise to alarm the advice of Sir William Willecox was sought, and he saw the case in consultation at 9.45 a.m. The condition was then as follows: pulse 148, respirations 48, temperature 101°, no reflexes present except the corneal, pupils small but not "pin-point," reaction to light just perceptible, crepitations and impaired resonance present at the base of both lungs. On the advice of Sir William Willecox lumbar puncture was performed and saline and glucose infusions continued. At 4.30 p.m. a further consultation was held, and the patient then exhibited a slight right plantar reflex; the corneal reflexes were brisk, and the pupils were slightly larger and sluggishly reacted to light. This improvement was attributed to the lumbar puncture. A further 12 c.c.m. of cerebro-spinal fluid was withdrawn, which, on analysis by Dr. Roche Lynch, was found to contain $\frac{1}{3}$ grain nembutal. Cardiac stimulants and further infusions were given, but at about 11 o'clock on the following morning the pupils became widely dilated and did not react to light, the pulse was imperceptible, and the patient died at noon.

As consciousness was not regained after administration of the anaesthetic the case was reported to the coroner and an inquest held. It was agreed that the cause of death was shock, some renal impairment due to ascending infection from the infected bladder, and the effects of nembutal. An estimation of the blood urea had been made at 6 p.m. on November 21st; this showed a concentration of 0.57 mg. per 100 c.c.m., so that renal deficiency was not serious. It is interesting to note that on a previous occasion nembutal had been given with no untoward symptoms. In this final operation the prolonged toxæmia from the pelvic suppuration, which began in June, 1932, had undoubtedly rendered the patient unduly susceptible to nembutal, so that a dose which would otherwise have been quite safe had a greatly enhanced effect, and produced a typical barbituric acid toxæmia with characteristic pulmonary congestion and bronchopneumonia.

The notes concerning this case are written with the agreement of Sir William Willecox, who on three occasions visited the patient in consultation.

The treatment of a case of narcotic poisoning consists in the administration of cardiac stimulants, intravenous infusions of saline and glucose (5 per cent.), and oxygen inhalations. Repeated lumbar punctures are valuable, as by this means cerebro-spinal fluid is withdrawn which contains a considerable amount of the narcotic, and which is replaced by fresh fluid of lower narcotic content. Frequent injections of strychnine have given good results in some cases (*British Medical Journal*, December 16th, 1933). In a case of veronal poisoning not less than 6 grains of strychnine were administered in sixty hours, and recovery ensued.

HEREDITARY SCOLIOSIS

BY

HUGH G. GARLAND, M.D., M.R.C.P.

HONORARY PHYSICIAN, LEEDS PUBLIC DISPENSARY AND HOSPITAL

There are now many well-recognized skeletal deformities in man which are inherited according to Mendelian law, and a large proportion of these are inherited as Mendelian dominants—that is, each affected person has an affected parent and an affected grandparent, and on the average half the children of an affected parent are themselves affected; among the commoner skeletal defects inherited in this way is brachydactyly.

One of the commonest deformities seen in hospital practice is scoliosis, the causes of which are numerous and often clearly understood, but there seems to be considerable doubt as to the importance played by heredity in the production of this condition. In 1896 Tubby (*Deformities*, p. 104) considered the hereditary factor to be common and important, and he quoted two families from his own practice in each of which several members were affected by scoliosis. Most authoritative articles on the subject mention the hereditary factor, but it is usually dismissed in a cursory manner. The discovery, then, of a family in which scoliosis is seen in five generations is important, especially as the deformity appears to be primary—that is, there is no recognizable disease of the nervous system (for we know that scoliosis is a frequent accompaniment of such hereditary diseases as Friedreich's ataxia and hypertrophic neuritis) or of the vertebrae.

As will be explained in the detailed description of the family the deformity in these cases has not been associated with any disability, and, indeed, several affected adults were not aware of their abnormality until I pointed it out. The pattern of the deformity is remarkably constant in all the affected persons, and it takes the form of the usual distortion of the thorax resulting from scoliosis. Briefly, there is a prominence of the ribs and costal cartilages of one side, affecting the lower more than the upper, the opposite side being flattened; the sternum, being rotated about its vertical axis, appears to be narrow; on the side of the prominence, which is well marked in the chondro-sternal junctions, the clavicle is raised, the shoulder being higher and straighter; the opposite clavicle is lower and not so prominent as its fellow; the angle of Louis is prominent. The degree of this distortion of the chest will, of course, depend on the position of the axis about which vertebral rotation occurs. In all these cases the scoliosis is either slight or not apparent on inspection, but it can always be seen by x-ray examination. The concavity is usually to the left in the lower dorsal and lumbar regions.

A,II,1 and A,I,1 and 2 are dead, but I,3, an intelligent man, who has appreciated his abnormality all his life and who has been carefully examined, assures me that his father and grandfather had exactly the same deformity, though it caused no disability; he says that his father, who died aged 65, was "affected on the left side." I,3 is a man of 64, and shows marked prominence of the left lower costal cartilages, starting at the third. His sisters and cousins have not been examined, but are said to be normal; I have written to I,1, who confirms that he has no deformity; I,5 and 6 say the same. I,2 died of cancer aged 55, and I,4 died aged 40. Nothing is definitely known of D,I,1, and D,I,2 is said to be normal. D,I,3 has been examined. She is a woman of 42 who has had a "pigeon breast" all her life; the left side of the chest bulges forward, although in this case the upper part of the chest is the most affected. D,I,4 was killed, aged 24, but the father is quite certain that the left side of the chest was affected. D,I,5 died aged 9 months and

nothing is known of him. D,I,6 died at the age of 36, and is said to have been normal. D,I,7 is 34, and has been seen; he knew nothing of his deformity, and again the prominence is on the left side. D,I,8, aged 32, has also been examined; she was said to be normal, and admitted that she had not noticed her deformity until it was pointed out to her. In this case the prominence is on the right side and is slight; there is no scoliosis obvious to the naked eye. She, like several of the others, has always had difficulty in getting her clothes to fit at the shoulders. D,I,9, aged 30, has been examined and is normal. D,I,10 has also been examined; in her case the right side is prominent, and she knows that the deformity has been present since birth. D,II,1 and 2 have not been seen, but are said to be normal. D,II,3, 4, and 5 were also said to be normal, but D,II,3, aged 12, was found to be affected on examination, the prominence

being right-sided and confined to the lower ribs; scoliosis was only demonstrable by x-ray examination. D,II,6, aged 15 months, has been examined, and is apparently normal.

It is interesting to note that I,3 shows two other congenital abnormalities. One is an accessory nipple on the left side, and the other is a "shagreen patch," of considerable size and similar to those so commonly seen in cases of epiloia, which lies symmetrically over the lower dorsal region. Similar abnormalities have not been seen in the other affected persons.

It will be seen that the deformity runs directly through five generations with the single exception of D,I,6; but this person is dead, and as D,I,8 had failed to notice her own deformity it is quite possible that D,I,6 was affected. This being the case, and considering the last three generations, there are sixteen children of affected parents; of these, eight are affected and three found to be normal on examination. In the case of the remaining five it is impossible to make a definite statement, but it is probable that the majority were unaffected. This gives as close an approximation to the 1:1 ratio as can be expected with such small numbers.

Here, then, is an example of scoliosis inherited as a simple Mendelian dominant, but the exact pathological anatomy is obscure. Radiograms have shown no structural defect in the vertebral bodies or intervertebral disks, nor have these patients shown any evidence of disease of the nervous system. So far as I know this is the first recorded example of scoliosis inherited as a Mendelian dominant, and it may give the clue to many cases of scoliosis of hitherto unknown origin.

It is proposed to hold an international congress of electro-radio-biology in Venice in September to study exclusively the biological phenomena caused by x rays and radium, independently of their application to medicine and therapy. The subjects to be discussed include the probable influences on organic and organized matter of the various rays, radiations, or radio-active salts in organic combinations, electric states of the atmosphere and their effect on biological conditions, and the question of the possible inheritance of such modifications. Further information may be obtained from Dr. Giocondo Protti, S. Gregorio 173, Canal Grande, Venice.

THE ORTHOPTIC TREATMENT OF SQUINT

BY

MONTAGUE L. HINE, M.D., F.R.C.S.

SURGEON, ROYAL WESTMINSTER OPHTHALMIC HOSPITAL

Considerable attention has been attracted during the past three or four years to the "orthoptic treatment" of squint. Under this title one includes not only the older and simpler methods of improving or maintaining the vision of the squinting eye (by correcting glasses, occlusion of the fixing eye, atropinization, etc.), but also, and more especially, the various methods of training the *desire* for binocular vision, where this is feebly developed or has lapsed from disuse, and of exercising the defective muscular movements of the eyes, which may be associated with squint. Much of the technique is well known and has been described previously, especially by Worth in his textbook on squint; but there are important improvements both in the instruments employed and in the methods used, which are of more recent development, and not so generally understood. This seems to be a suitable opportunity to indicate the general lines of such treatment as it is at present employed, and to give some idea of the cases in which it is likely to be of use. Much of the information has been obtained from the Orthoptic Department of the Royal Westminster Ophthalmic Hospital, which hospital, in 1929, was the first in this country to organize such a department.

GENERAL INDICATIONS

For satisfactory results to be obtained it is necessary to select suitable cases. There should be good fixation with the squinting eye, and, if the child is old enough to be tested, the corrected vision of this eye should not be less than 6/18. The child should be at least 3 years old, but under 7. Over this age results are much less favourable, though not by any means entirely, or uniformly, negative. All patients should have their refractive error almost fully corrected. The best results are obtained in convergent squint; cases with a vertical deviation in addition are less favourable, many of these not being true concomitant squints, but having a parietic element. Even in such cases, however, it is sometimes found that the vertical deviation disappears during treatment. Myopic divergent squints, which develop later in childhood, and which glasses alone have failed to cure, usually respond satisfactorily; the divergent squints which are not due to refractive errors, and which usually develop in infancy, are seldom benefited, probably because there is a very weak inherited desire for binocular vision. True alternating squints, also, are not very satisfactory for training for the same reason.

THE SYNOPTOPHORE

The instrument which is used in many of the orthoptic clinics in this country is the synoptophore, an elaborate development of the original amblyoscope, described and used by Worth. Like the amblyoscope, the synoptophore consists of two angled metal tubes, each with a mirror, set inside at the angle, to reflect the image of the picture, placed in the slot at the distal end of the tube, through a convex lens, set in the eyepiece, into the patient's eye. Each tube can be moved separately on the base of the instrument to suit any angle of squint. The angle of deviation can be read off on a scale attached to the base; vertical deviations can be read off on a vertical scale. An electric lamp, controlled by a rheostat to vary

the intensity of the light, is set inside each tube to illuminate the picture. In the most recent models, to provide additional interest for the child, there is a mechanism for showing specially prepared "moving pictures." One important difference between this instrument and the amblyoscope, or ordinary stereoscopes, is that an unimpeded view of the patient's eyes is obtained by the trainer, who is seated on the opposite side of the instrument. Special stress is laid on this, as it has been found that some 70 per cent. of squinters do not, at first, obtain binocular vision at the true angle of their squint, but get simultaneous vision, or even fusion, when the squinting eye is still squinting a variable degree, often 10 degrees. This deviation cannot be detected by instruments which are controlled by the patient himself, in which the position of the eyes cannot be watched, and if fusion training is started without true binocular macular fusion, the result is likely to be unsatisfactory, as the faulty habit of obtaining binocular vision with the eyes still squinting becomes harder to correct after it has been thus encouraged.

TECHNIQUE

The true angle of the squint must therefore be first determined. This is done by finding the position of the tube opposite the squinting eye, in which the corneal reflex from the light in the tube is exactly symmetrical with that in the fixing eye. The angle is then read off on the scale. Any vertical deviation is similarly measured by adjusting the tube vertically, and taking the reading on the vertical scale. If it is found that the child has simultaneous perception of pictures, such as a lion on one side and a cage on the other, while the squinting eye is still partially deviating, as can be determined by the position of the corneal reflex, and does not see both pictures at the same time when the one before the squinting eye is placed at the true angle of the squint (in which position it is thrown on the macula), then there is false binocular projection. This must be remedied, if possible, before further training with the synoptophore, or any exercises with an amblyoscope or various kinds of stereoscopes, can be undertaken. This is effected by making the patient fix a well-illuminated picture with the squinting eye. While all his powers of concentration are focused on this picture, the tube containing the picture before the other eye is slightly moved rapidly from side to side, varying the illumination if necessary, until he gradually becomes able to appreciate both pictures nearer and nearer the true angle of the squint, and finally is found, on the instrument, to have true binocular projection, with the pictures accurately focused on each macula.

When this stage has been reached exercises are carried out to develop this true binocular vision under more difficult conditions of illumination, by varying the intensities of the lights, until the patient ultimately sees both pictures simultaneously under all conditions of illumination. The contrast between the pictures can be similarly varied. The pictures used with the synoptophore, as with the amblyoscope and various stereoscopes, are of three classes: (1) Those which require simultaneous vision only, and no fusion—for example, a lion on one picture and a cage on the other. (2) Those which require some sense of fusion to make a complete picture—for example, a man in one picture with arm and leg missing, these parts being supplied, with some parts common to the first picture, by the second. (3) Those which require a sense of perspective—true stereoscopic vision, which is necessary for the most accurate judgements of depth and distance.

Having developed good simultaneous perception the trainer shows pictures of the second group, and, when

good fusion has been obtained under all conditions of illumination and contrast, the range of fusion is increased by slowly moving the tubes through smaller or greater angles, until the limit has been reached at which the picture still continues to be seen as a whole. When a good range, or amplitude, of fusion is present, it is usually possible for the patient to have a sense of perspective, and this is trained and developed by pictures of the third group.

RESULTS

The cure is complete when the child has become so desirous of this good vision, and the muscles, by the exercises, have been strengthened sufficiently to enable him to overcome the deviation owing to this unconscious or conscious desire, that he habitually ceases to let one eye squint. Many patients, of course, do not attain this ideal, and others require operation. If it is found that good binocular vision can be obtained while the patient has the strong stimulus for such vision, which is supplied by the interesting pictures shown him on the various instruments, but that, under normal conditions of life, the squint still persists, operation should be undertaken at the earliest possible age, to approximate the visual axes more nearly to normal: The desire for fusion, already shown to exist, will then overcome any slight imbalance that may still be present. Such operations are preferably done before the age of 7, and must then be performed under general anaesthesia, when one cannot so accurately control the result of the operation as under local anaesthesia. Hence it is only in cases in which useful binocular vision is expected to result that one should operate under general anaesthesia and hope to gain perfectly satisfactory results. However, when an "inferiority complex" is developing in a young child, or even in the mother, as the result of the squint, an operation may be undertaken, even without such expectation, in order to improve the appearance of the child. Except in such cases, purely cosmetic operations should be left until the child is old enough to have one carried out under local anaesthesia.

After operation undertaken for the purpose of obtaining binocular vision, a few further exercises should complete the cure of the squint. If the operation is delayed until 7 years of age or more, the prospects of such a complete cure are remote. No treatment session should be continued too long, or the child will lose interest; half an hour is the limit. The exercises may be varied by using other instruments, once the "binocular projection" is true. The cheiroscope, with which the fingers are used to draw pictures, to pick-up various objects, etc., while the child is being unconsciously educated to use both eyes at the same time, is a useful variant, as also are the ordinary stereoscopes and the "drawing" stereoscope; these can be used for home training. To improve the action of individual muscles or groups of muscles another apparatus, the myoculator or the myoscope, may be used. A double picture, requiring fusion, is projected on to a screen, and moved backwards and forwards in any required direction.

The time taken for such training varies considerably. Forty sessions are frequently required, sometimes more, sometimes only twelve. Considerable patience on the part of the trainer is obviously required, and the necessary skill can only be obtained under competent instruction. For practical reasons such treatment is frequently impossible, but there is no doubt that it is of great benefit in suitably selected cases, and that its recent development in hospitals and private clinics has proved of considerable service to ophthalmology.

EPIDEMIC JAUNDICE IN NORTH LEICESTERSHIRE

BY

T. MCCOWATT MONTFORD, M.B., CH.B.GLAS.
MEDICAL OFFICER OF HEALTH FOR THE CASTLE DONINGTON
RURAL DISTRICT

Outbreaks of infective jaundice are comparatively common in Britain, and have been reported on from time to time.

Cockayne¹ (1912) described two types of the disease. The more severe form he styled "infectious jaundice" (the so-called Weil's disease), and the other milder condition "epidemic catarrhal jaundice." In the severe type Inado and Ido² (1915) discovered *Leptospira icterohaemorrhagiae*. *Leptospira* were found by Elliott and Beattie³ (1932) in the Selkirkshire epidemic. Buchanan⁴ (1927) obtained *leptospira* in the urine of seventeen cases, and produced spirochaetal jaundice in two guinea-pigs by inoculating them with the urine of infected patients. Morgan and Brown⁵ (1925) were unable to demonstrate this organism in the cases they investigated in Northamptonshire. No causal agent was identified in the Surrey epidemic by Findlay, Dunlop, and Brown⁶ (1931).

The symptomatology in these and other British epidemics did not greatly vary, and it would seem that such epidemics are manifestations of the one disease, although a spirochaete or other organism could not be constantly demonstrated.

An epidemic occurred in Castle Donington, North Leicestershire—a country town of 2,674 inhabitants—in the eight months from February to September, 1933. Forty-five cases were identified as acute infective jaundice—twenty-four by me and twenty-one by my partner, Dr. W. H. Dowell. This article deals exclusively with the former twenty-four cases—twelve of each sex.

With the exception of two, all affected persons were children. There were no deaths.

The condition has been frequently described, and it is not proposed to give the records of individual cases. Two, however, are of interest, as they were characterized by manifestations of unusual nature.

The course of the disease, except in these two instances, varied but slightly from that described by other recorders: anorexia marked the onset, and generally this was associated with lassitude, and sometimes with prostration and a feeling of weakness in the lower limbs. Two children complained of giddiness. As a rule fever was slight or absent. Either constipation or diarrhoea was evidenced. Vomiting occurred in all except three cases, and lasted for several days. From three to seven days after the initial symptoms, and from two to three after the onset of vomiting, bright yellow jaundice appeared and quickly spread over the body surface, persisting for a period which varied with the severity of the individual attack. A boy of 4, it is interesting to note, complained of "seeing green." The tongue was furred, and the abdomen occasionally distended. Pain and tenderness were common in the epigastric region, the tenderness being greatest towards the duodenal side. The faeces were clay-coloured in every instance, dark motions intervening from time to time. Enlargement and tenderness of the liver were observed in several cases, and in two patients the spleen was increased in size. Bile was always present in the urine, and remained for long periods after the jaundice had disappeared. Albumin and urates were generally found. In only two cases was the urine examined bacteriologically. The microscopical examination of centrifugized deposits, made at the Leicestershire county laboratory, showed no *Leptospira icterohaemorrhagiae*, but there

were large numbers of Gram-negative bacilli; on culture there was an acid and gas formation in lactose litmus broth which was suggestive of *B. coli*. As the urine was originally alkaline it was thought, the reports stated, that a large number of the Gram-negative bacilli were *B. proteus vulgaris*. Photophobia, cervical adenitis, and morbilliform rashes occurred, but were unusual. The infection was apparently distributed by personal contact. Salol was the drug most generally employed, but it was not certain that it influenced the course of the disease.

CASE I

The first case referred to was a girl aged 4. The attack was ushered in by malaise and vomiting on April 17th. The vomit contained bile, which at first was mixed with food. I was called in on the 19th, when there was slight jaundice, the tongue was furred, the temperature 103° F., the pulse raised, the liver enlarged and tender, the spleen easily palpable, and the motions constipated and almost white. Vomiting was severe, and was not relieved until the 27th. Even peptonized milk was not retained until after four days of treatment. The liver became normal in size on the 29th, but jaundice was still present. On May 5th a morbilliform rash appeared, and persisted for six days. This was associated with a cough, and moist rales and rhonchi could be heard on auscultation. Four days after the disappearance of the measles-like rash the temperature rose to 101°, and there was an urticarial eruption over the body and limbs which remained for five days. Conjunctival jaundice still lingered on until May 25th—twenty-seven days after its initial appearance. Two days later, however, there was a recurrence of vomiting, with epigastric pain and loose, pale stools. The temperature was subnormal but the pulse rapid. Urticaria again developed, and was quickly generalized. It was once more present for five days. Vomiting ceased at 8 a.m. on the 29th, but the motions were loose until June 5th. As bismuth was being administered it was impossible to ascertain when the colour of the motions would have become normal. Bile was still present in the urine.

CASE II

The second case, in which atypical symptoms arose, was a married lady who was approaching the menopause. She

Electrocardiographic tracing from the second case, indicating myocardial disease.

felt chilled on May 9th, and on the following day vomiting and diarrhoea commenced. The temperature was 100° F., and the pulse 120. Backache and epigastric pain were marked. On the 11th the diarrhoea and vomiting became more troublesome, and there was then hepatic enlargement and tenderness. The spleen was painful on palpation. The temperature was unchanged, but the pulse was now 100. The motions were pale, and the diagnosis of infective jaundice was made, and, on the day following, confirmed by the appearance of an icteric tinge in the conjunctivae. Jaundice, although not intense, was soon widespread, and lasted for eight days. Bile and albumin were present in the urine. The temperature and pulse were normal on the 16th, and the clay-coloured stools became darker and less loose, but the tests for the presence of bile and albumin in the urine were still positive. The course of the disease was apparently satisfactory until,

on the morning of the 23rd, there was sudden stabbing precordial pain, which passed backwards to the angle of the scapula and upwards into the shoulder. There was great dyspnoea, and the face was ashen. The pulse was poor in volume and rapid. In consultation with Dr. Hugh Barber of Derby the condition was diagnosed as myocardial infarction, and this was considered to be substantiated some months later when the consultant, on making an electrocardiographic examination, found evidence of myocardial disease. In the tracing (which is reproduced herewith) the ventricular R wave in lead II presented well-marked notching.

I wish to express my indebtedness to Dr. J. A. Fairer, the county medical officer of health, for his reports on the two samples of urine, and to Dr. Hugh Barber for his report on the electrocardiographic examination, which he carried out.

Clinical Memoranda

A SYMPTOM OF POISONING BY HYPNOTICS OF THE BARBITURIC ACID GROUP

Poisoning by members of this group is now so common that it has become the subject of frequent comment, not only in the medical journals, but in the lay press also. While the ordinary symptoms are well known, there is one symptom which has never been stressed in publications on the subject, but which may nevertheless explain some of the acute and even fatal cases of poisoning which otherwise appear unaccountable. This symptom is perhaps most easily described by reference to the following three cases:

1. A professional man, aged 42, was taking dial tablets (each 1½ grains) for insomnia. He took one tablet and, failing to fall asleep, took a second. From that time he lost all knowledge of what he was doing, and apparently went on taking further tablets at intervals until he had emptied a complete tube of ten. He slept for thirty-six hours, and on waking had no recollection of taking more than two of the tablets.

2. A nurse, aged 35, had a precisely similar experience, also with dial, in her case emptying a tube in which were eight tablets, again without any recollection of having taken more than two.

3. Another professional man, aged 76, who was in the habit of taking veronal (7½ grain tablets) swallowed in a similar way eight of these tablets, and after sleeping for twenty-four hours assured me he had had only two, at intervals of one hour between the doses.

For this symptom I have borrowed the term "automatism," as that seems to explain best the process involved. It would appear that the knowledge of the need for another tablet persists, while the memory is so affected by the drug that the patient does not realize that he has already satisfied the need, and automatically repeats the dose at intervals. Though all three patients recovered it has to be noted that in each instance the available supply was exhausted, and had a larger quantity of the drug been at hand there is no reason to believe it would not have been all taken, with possibly fatal result.

The occurrence of such a symptom adds materially to the risk of exceeding moderate doses in the use of drugs of this class.

ROBERT RICHARDS, M.D., F.R.C.S.Ed.,
Lecturer in Forensic Medicine,
University of Aberdeen.

SUBACUTE INVERSION OF THE UTERUS

The extreme rarity of the condition known as puerperal inversion of the uterus—authorities giving estimates of its incidence varying from anything between 1 in 27,000 and 1 in 190,000 labours—prompts me to report the following case.

On November 17th, 1933, I was summoned by a colleague to see a woman, aged 34, whom he had delivered of a healthy child (her second) on November 14th. The placenta had been adherent, and he had found it necessary to remove it manually, but apart from this he had not noticed anything abnormal at the time. The patient, however, continued to lose steadily, and the practitioner sent for me as he could feel a mass in the vagina, which he thought might be a large fibroid polypus, since the uterine fundus was high. On abdominal examination the "fundus" was half-way between the umbilicus and the ensiform, but the exhibition of a catheter resulted in three pints of urine, and the tumour disappeared. The dimpling where the body of the uterus should have been was then apparent, and vaginal examination confirmed the diagnosis of a nearly complete inversion, the thinned-out rim of the cervix being just felt in the vaginal vault. The patient's condition was very poor. She had obviously lost a lot of blood, and the pulse was thin and frequent. There was no pyrexia.

Under a general anaesthetic I attempted reduction, but all my efforts were unavailing, the retraction ring in the lower uterine segment obviously blocking the way. I therefore packed the vagina, and had the patient removed to the Royal Salop Infirmary. I did not feel justified in pursuing expectant treatment—for example, by Aveling's repositior, which is advised in the first instance where reduction cannot be effected immediately after onset—seeing that the woman was slowly and surely bleeding to death. I therefore had her prepared for laparotomy, but made another trial of reduction per vaginam, which proved as abortive as the first. I then opened the abdomen, and saw the typical picture of tubes, round ligaments, etc., disappearing into a crater formed by a hard, thick ring. By means of taxis with my right hand in the vagina, at the same time incising the posterior sector of the contraction ring with a scalpel in my left, I had the satisfaction of seeing the uterus gradually evaginate and assume its normal contour. In this connexion I consider it preferable that the operator, rather than an assistant, should undertake the intravaginal manipulation, as by this means the requisite amount of pressure (and it is considerable) can be more accurately gauged. Any undue force, it is hardly necessary to remark, may be attended with disastrous results.

The operation was completed by repairing the incision in the posterior uterine wall, the wound being about three inches long and extending deeply into the musculature, and closing the abdomen. This procedure, attributed to Haultain, is well figured and described in the latest edition of the *Combined Textbook* emanating from the Scots school. Finally, the patient was placed in the lithotomy position, thoroughly douched out, and given an intrauterine swabbing with glycerin and iodine.

The patient did remarkably well. There was a good deal of distension on the third day, and the temperature rose to 100.2° F. By the fifth day, however, the temperature had settled down to 97.2°, and all immediate anxiety was at an end. The lochia were slight, and never at any time offensive. On the thirteenth day the patient had a rigor, and the temperature rose to 102.4°; from that day onwards, however, it came down steadily, reaching normal on the eighteenth day and remaining so. I could find nothing to account for this pyrexia, and ascribed it to a mild pelvic thrombophlebitis, a not unexpected sequel to manual removal of the placenta. There was no sign of phlegmasia. Subsequent convalescence was uneventful, and the patient returned home after five weeks, with no more than a slight anaemia remaining. I understand that she suffered some oedema of the legs when she started to move about her house, but this has now completely vanished. She has had one normal period.

The only other comments I have to make are: (1) the retention of urine is not surprising having regard to the

altered anatomical relationships; and (2) I do not believe the more or less complete inversion occurred at the time of placental removal. The attending practitioner certainly did not see the inversion, and I am of opinion that a slight dimpling took place, which later progressed to the full condition, the uterus being in a flabby state. On these grounds, and also from the fact that treatment was not instituted until the fourth day, I have labelled the case "subacute."

R. L. E. DOWNER, M.D., M.C.O.G.,
Honorary Obstetric Surgeon, Royal
Salop Infirmary.

A CASE OF CANCER TREATED BY SURGERY,
RADIUM, AND DIATHERMY

It is often difficult to follow up cases for a sufficient period to make the estimation of treatment of practical value. The case I am reviewing has been under my care for nearly seven years, and has a very important bearing on the value of the three means of treatment mentioned above in certain types of carcinoma. I am sure the patient would not now be alive and in good health had it not been for this combined method of treating her.

Miss A. M. J., aged 58, consulted me on December 13th, 1926, for uterine haemorrhage. Her menopause was passed many years ago. She had had three days of bleeding just prior to seeing me; there had been nothing of the sort for years, and she had had no vaginal discharge. I found the uterus freely mobile, but somewhat enlarged; the vagina and cervix appeared healthy, and no blood was seen. On December 17th I curetted the uterus in a nursing home. The curettings were massive, and left little doubt as to the nature of the disease: the pathological report stated the case to be one of columnar-celled carcinoma of the uterine body.

On December 22nd, 1926, I performed a panhysterectomy. The uterus showed a carcinoma involving quite half of the uterine cavity, and eating its way almost through to the peritoneum. From this operation she made a good recovery, and I did not see her again until August, 1928, when she came complaining of a blood-stained vaginal discharge which had existed for a month or two. Examination revealed a friable mass of growth in the vaginal vault which bled freely on touch; it proved to be a recurrence of the carcinoma.

The future of the case now seemed hopeless. I considered any extensive surgical removal out of the question; the only hope appeared to lie in the direction of radium and diathermy, and these might only tide the case over for a time. However, I removed the mass with a curette, and then used the diathermy all over the vault at the same operation. Some days later I packed a tube of radium up against the vaginal vault for twenty-four hours. Following this the healing was perfect; nothing was left but a clean white scar. Five months later the condition was the same. All the parts looked healthy and healed; but I did not trust it, and again packed in a tube of radium.

I saw her at intervals, and all seemed well until January, 1931. A nurse who had kept in touch with her then reported to me that there was a renewal of the vaginal haemorrhage. I examined the patient, and to vision and touch there was nothing to account for the bleeding. The vaginal vault was firmly healed and dry. The question of possible vesical haemorrhage arose, but examination of the urine revealed no sign of blood or growth. However, ten days later it became evident that the blood was coming from the bladder, and examination with the cystoscope showed a single sessile papilloma of small size, from which the blood originated. This I destroyed by means of a diathermy electrode passed through the cystoscope. I examined my patient a few days ago, and found her well and free from any signs of carcinoma or bladder papilloma. The latter growth had, I am sure, nothing to do with the former, from which she had been free for five years.

Reviews

DR. ADDISON'S DIARY

The general make-up of the Right Hon. CHRISTOPHER ADDISON's personal diary from June, 1914, to January, 1919, entitled *Four and a Half Years*,¹ is not attractive. This first volume, which takes us to the end of 1916, is heavy to handle, and printed closely in smallish type on not very agreeable paper. It is embellished with a considerable number of illustrations consisting mainly of portraits either of men whose portraits are already very well known or of others whose importance is scarcely such as to require their inclusion, together with a few other pictures of incidents of no very pronounced interest. There has been some inattentive proof-reading, and the mistakes made in the names of persons mentioned are amazing. Thus, Sir James Leishman is called William, and to instance two members of the British Medical Association whose names should be well enough known, we have a reference in one place to Dr. Arthur Cox and in another to Dr. Brackenberry.

On the whole, though it contains a number of scattered interesting passages, the book is rather on the dull side. Compared with the two recent publications of Lord Riddell and Mr. Lloyd George, covering much the same period, it fails to grip the attention except here and there, and at times becomes tedious. This comparison is, however, scarcely fair, for those two books were published first, and have already told us much of what we wanted to know, and the present author's position throughout the greater part of the period, though creditable and influential, was subordinate. He does not seem to provide us with any revelations or striking new facts. His diary is, indeed, too long. Though it would, of course, have been improper to falsify notes made at the time or to adjust the immediate expression of opinion in the light of later events, there could surely be no objection to lightening the book by the omission of sheer trivialities, which abound, or of ill-natured remarks about persons quite unimportant in this connexion, to whom or to whose relatives they can now only give pain without any compensating public advantage. Dr. Addison thinks it worth printing of a certain clergyman that "the good man is rather a bore," and of a certain provincial mayor that he was "the limit of mayors encountered to date. It was suggested that he might have a course in an M.D. school," and worth recording that one day he got "up late and pottered about the garden." There is one passage in which the author expresses in rather exaggerated language a contemptuous opinion of the British Medical Association, and another which implies his belief in the success of a much smaller and less important medical organization. His judgement was evidently sometimes at fault, and it might be amusing to have a printed record of the view which certain of those whom he vilifies took of Dr. Addison.

The earlier part of the diary will be of most interest to readers of this *Journal*, and has an appreciable value. It relates mainly to the proposals for educational and health advance made in 1914 and the early part of 1915, and to the establishment and early work of the Medical Research Council. We are reminded of the difficult circumstances which these movements encountered, and these chapters reveal the author as a stout, zealous, indefatigable, forceful and, on the whole, wise protagonist for public health, educational advance, and fruitful scientific research. He pays a fine tribute in this con-

nexion to three great men with whom he was associated—Lord Moulton, Sir Walter Fletcher, and Sir Robert Morant. Of the last-named he says: "The man, of all others, who helps is Morant—great and keen and willing to take no end of trouble. . . . Morant is a king among public servants. . . . A great administrator, but, for all that, bubbling over with enthusiasm to get a 'move on' with things." This is well said. Dr. Addison also fitly acknowledges the helpfulness and fine work of Sir George Newman. A sidelight on the difficulties of progress in the fields with which he was most concerned is thrown by the author's account of what he calls these "everlasting departmental wrangles," for which he displays a very creditable contempt and impatience. They were mainly, at that time, between the Local Government Board and the Board of Education. Dr. Addison's efforts towards conciliation and adjustment were praiseworthy, and occasionally successful. It is pleasant to know and to acknowledge the services he rendered in saving, under very discouraging conditions, what could be saved of proposals for health provision and scientific research, some of which have already proved to be of inestimable value. The publication of his second volume, which will presumably contain an account of his activities as Minister of Reconstruction and the establishment of the Ministry of Health, will be anticipated with pleasure.

OPERATIVE GYNAECOLOGY

Gynécologie Opératoire,² by Professor HENRI HARTMANN, has been out of print for some time, and the second edition has been largely rewritten, although the original form of the book has been preserved. It is divided into five parts: the first deals with the examination of the patient, physical treatment, and minor gynaecology, the second with operations on and through the vagina, the third with those performed by the abdominal route, the fourth with therapeutic indications in diseases of the genital tract, and the fifth with the surgery of the urinary tract. It is apparently the custom in France to make vaginal, and even rectal, examinations without protecting the fingers with gloves or finger-stalls, otherwise the practice described in the first part does not differ widely from that observed in England.

The chapters on operations on and through the vagina are perhaps the most interesting, but it is surprising that so much space should be devoted to the various interposition operations, and to hysterectomy by the perineal and parasacral routes. It comes, moreover, as somewhat of a shock to read that Professor Hartmann thinks it necessary to leave four clamps on the uterine pedicles after performing vaginal hysterectomy. The feature of the third part of the book which strikes the English reader is the frequency with which resort is had to drainage. The author himself attributes his good results for hysterectomy largely to the fact that he drains either through the vagina or the abdomen, depending on whether the total or the subtotal operation is performed. This fact probably accentuates the difference between the operating theatre technique in France and England rather than that between the surgeons. It is further revealed that there are still some surgeons who close the abdominal incision in one layer. In the author's opinion, not only carcinoma of the body of the uterus, but also early cases of carcinoma of the cervix, are best treated by hysterectomy, and he favours the vaginal route. In the section devoted to the surgery of the urinary tract the direct method of cystoscopy developed by Kelly in America is enthusiastically recommended.

¹ *Four and a Half Years*. A personal diary by the Right Hon. Christopher Addison, P.C., M.D., F.R.C.S. Vol. i. 1914-1916. London: Hutchinson and Co. 1934. (Pp. 297. 18s.)

² *Gynécologie Opératoire*. Par Professeur H. Hartmann. Second edition. Paris: Masson et Cie. 1933. (Pp. 583; 478 figures. 116 fr.)

It would appear that nearly every gynaecological operation was first performed in France, and even the Alexander-Adams operation is "sometimes" called the d'Alquié-Alexander-Adams operation! The illustrations are moderately good, but that on page 316 depicting the median abdominal incision is valueless, and misleading in nearly every detail. The book is too advanced for the medical student, but gives a splendid idea of the range of gynaecological operations practised in Europe. Whether it is due to the French language or to the logical Gallic mind the fact remains that much information is presented in a compact form, and yet everywhere the sentences flow smoothly and are a pleasure to read. The binding is unworthy of such a volume.

LEGAL ASPECTS OF MENTAL ILLNESS

Under the title of *Legal Aspects of Mental Illness*³ Mr. GATTIE has rewritten and enlarged the second edition of his *Lunacy Practice, Certification, and Detention*, a change of title obviously necessitated by the new provisions of the Mental Treatment Act of 1930. Also a chapter has been added dealing with testamentary capacity and the appointment of a receiver. The Mental Deficiency Acts are not included in the work.

The first and second editions are well known as useful summaries of procedure, especially to the general practitioner when confronted with the certification of a person of unsound mind. In this, the third, edition particular interest naturally attaches to the new provisions in respect of voluntary and temporary patients. Here there is admirably clear and concise guidance to the whole procedure under Sections I and V of the Mental Treatment Act. It may be recalled that Section I extends to public mental hospitals permission to admit voluntary patients without any form of certification, a means of care and treatment previously limited to certain institutions for private patients; whilst Section V allows persons suffering from mental illness who are likely to benefit by temporary treatment, but are for the time being incapable of expressing themselves as willing or unwilling to receive such treatment, to be admitted for treatment into mental institutions, approved hospitals, homes, etc., on application and medical recommendation, but without certification. Steadily increasing advantage has been taken of the provision in regard to voluntary patients in public institutions wherever accommodation has been sufficient and proper; but there can be no doubt that the response to Section V, for one reason or another, has been most disappointing. In this connexion the author refers to the wording of Section V, which, he says, cannot be regarded as a triumph of draftsmanship, and adds that it is a subject for obvious comment that the words "capable" and "incapable" should have been omitted to be defined in the interpretation section. It is probably true that there are still widespread doubts as to the kind of case which would be officially regarded as properly falling within the operation of this section and consequent failure to take advantage of its benefits. For this reason this little book will be found of much help. At the same time it should be pointed out that the official returns published by the Board of Control show that in certain, and presumably more enlightened, districts very considerable advantage is taken of this section—in fact, greatly in excess, of the 5 per cent. of all admissions quoted by Mr. Gattie in a footnote as the probable maximum of its utility.

The book is well indexed and carefully documented, and excellently incorporates the practice under the Lunacy and Mental Treatment Acts, 1890-1930.

³ *Legal Aspects of Mental Illness*. By W. H. Gattie. Third edition. London: Shaw and Sons, Ltd. 1933. (Pp. 86. 7s. 6d. net.)

BACTERIOLOGY FOR MEDICAL STUDENTS AND PRACTITIONERS

The object of this book⁴ by Dr. A. D. GARDNER is to present the subject of bacteriology "shortly, readably, and relevantly." This is no mean task. It is so difficult to know just how much may be safely left out, and, this having been decided, how to weave the selected facts into an attractive story in which each one gets its correct value. However, Dr. Gardner has succeeded admirably. He starts with four chapters of a general nature explaining the significance of bacteria, their form and structure, the methods of cultivating them, and their pathogenic action. Following this the different pathogenic bacteria are described, each genus being given a separate chapter. Then there is a chapter devoted to pathogenic protozoa and fungi, a good short account of filterable viruses, and, finally, chapters on immunity and on the prevention of infection.

There is little to criticize. An obvious slip occurs in Table XVI, where the pathogenicity of the human and bovine types of the tubercle bacillus is given incorrectly, and some might object to the inclusion of Banti's syndrome and acholuric jaundice as fungoid conditions, even though the author has only done this provisionally. And in such a rapidly growing subject as filterable viruses it would indeed be difficult to write a general account which would satisfy everyone. It is doubtful, however, whether the author's view that characteristic form is one of the chief attributes of life would meet with general approval, and it is difficult to understand why the diagnostic value of the complement-fixation reaction, with the sera of chicken-pox and herpes convalescents, should be considered as of doubtful value (Table XXIV). These are minor points, however. The book is a good one, and appropriate to the purpose for which it has been written.

EARLY OPHTHALMOLOGY

A fourth volume of the Short History Series has been written by Mr. ARNOLD SORSBY dealing with ophthalmology.⁵ In the limited space of one hundred pages the author has contrived to give a thoroughly readable, informative, and balanced account of the gradual rise of the knowledge of the structure, functions, and troubles of the eye. He gives the reader a brief summary of eye treatment in the Ancient East, in the Greek and the Arabian periods, and in the West in the Middle Ages and since. He deals severally with the growth of knowledge of the anatomy, physiology, and pathology of the eye, and subjects such as cataract, glaucoma, therapeutics and spectacles, and the ophthalmoscope receive separate chapters. Finally, there is a chapter on ophthalmology in the British Isles.

In these days when, to quote the author's words, "the ophthalmoscope has raised ophthalmology to the most exact of clinical studies" one is apt to forget the difficulties of our forefathers in medicine. They were not a little handicapped by the penalties which popular prejudice attached to an untoward result that might have attended any treatment other than the "expectant!" The provisions of the code of Hammurabi some 2000 years B.C. were not calculated to foster daring treatment. The code enacted that for a successful operation which saved the patient's eye the fee should be ten shekels of silver in the case of a "gentleman," but only five shekels and two shekels in the case of a poor

⁴ *Bacteriology for Medical Students and Practitioners*. By A. D. Gardner, D.M., F.R.C.S. Oxford Medical Publications. London: H. Milford, Oxford University Press. 1933. (Pp. 276. 6s. net.)

⁵ *A Short History of Ophthalmology*. By Arnold Sorsby, M.D., F.R.C.S. With a foreword by R. Rutson James, F.R.C.S. London: John Bale, Sons and Danielsson, Ltd. 1933. (Pp. 103. 3s. 6d. net.)

man and an "owned" slave respectively. For an unsuccessful operation on a freeman causing death or the loss of the eye, the surgeon should have his hands cut off; in the case of a slave the penalty was replacement of the slave with another. The chapter on ophthalmology in the British Isles will be of special interest. It is full of quaint humour. Noteworthy is the translation by Richard Banister of Jacques Guillemeau's *Maladies de l'Oeil* in 1662. To the translation he added a *Breviary*, "something of mine own, that through my experience they may find at last, what I was learning long." Therein Sorsby found a most significant passage, one in which the hardness of the eye was described as a diagnostic and prognostic feature in the treatment of gutta serena—an observation that fell on stony ground and had to be rediscovered in the nineteenth century.

In any subsequent edition the author might well add a paragraph on the romance of the discovery of "retinoscopy" for refraction. Bowman saw the variation of the light reflex, and told Donders of it; the latter noted this in his book, but neither followed up the observation. Caignet, an obscure French ophthalmologist, discovered it for himself, and worked out its implications. But his knowledge of optics was so poor that his papers seemed nonsense. Not until Parent of Paris investigated the claim was the amazing secret displayed; it then received immediate and world-wide adoption. Mr. Sorsby's little book has been well done; it provides a pleasant evening's reading for both ophthalmologist and general practitioner, and withal is a convenient source of reference.

RAMÓN-CAJAL'S "HISTOLOGY"

RAMÓN-CAJAL'S *Histology*¹ is now in its tenth edition. It is the standard work on the subject in the Spanish language, being in use in practically all the Spanish universities, and its author is recognized as the most distinguished histologist of modern times and the discoverer of the neurone structure of the nervous system. Yet the book is unknown in this country, except probably to one or two who understand the Spanish language. Dr. Fernán-Núñez has now translated it into English, and readers will thus be able to form an estimate of the great debt which histology owes to Ramón-Cajal and his disciples. The book reflects the particular features of the method of teaching histology in the Spanish schools, which differs in some important respects from the methods in use in this country. During the first year the medical student is given a thorough grounding in cytology, its history and philosophy. The normal histology of the tissues and organs is then taken up with their histopathology during the second year. From a biological point of view this method has much to recommend it, and English students might with advantage receive more instruction in cytology than they do at present, if they could find the requisite time. But with regard to histology it does seem desirable, from a purely medical standpoint, that the student should already have some general knowledge of pathology when commencing the study of histopathology. The cytological part of Ramón-Cajal's book is an exhaustive treatise on cells and their intimate structure, and it is illustrated by numerous beautiful photomicrographs. The second part of the work, dealing with the histology of the tissues and organs, is specially noteworthy for the minute and elaborate description of the structure of the nervous system. A valuable appendix on histological methods concludes the volume. The excellent portrait of Ramón-Cajal, inserted as a frontispiece, forms an attractive feature of the book.

¹ *Histology*. By S. Ramón-Cajal, M.D., F.R.S., J.L.D. Revised by J. F. Fello-Méñor, M.D. Authorized translation from the tenth Spanish edition by M. Fernán-Núñez, M.D. London: Baillière, Tindall and Cox. 1933. (Pp. xiv + 738; 535 figures. 40s.)

BRITISH HEALTH RESORTS

We have received a copy of the 1934 edition of *British Spas, Inland and Seaside Resorts*, being the official handbook of the British Health Resorts Association Limited. As before, it is edited by Dr. R. FORTESCUE FOX and published by Messrs. J. and A. Churchill, at 1s. net. There are several new features. The Minister of Health contributes a "Foreword" wishing the association every success in its work, and pointing out that it fulfils a real need in directing, under responsible medical guidance, the attention of doctors and the public to the advantages of the home resorts. On page 5 is a brief statement of the conferences and meetings which the association has held, followed by an expanded statement on the uses of spas in general and the British spas in particular. For the first time attention is called in detail to the health attractions of the Dominions of New Zealand, South Africa, and Canada. The information in this handbook is compiled from official sources, and on the medical side has been carefully revised by the Medical Advisory Committee, with the assistance of medical officers of health and local professional bodies. A new section has been added on "The Seaside 'Cure,'" and the seaside resorts are now dealt with under their respective "regions," preceded in each case by a new map giving much useful information as to aspect, altitude, configuration, etc.—items of great value in deciding the proper venue for different individuals seeking health and convalescence.

Notes on Books

Those who are interested in children's sleep and who feel that they would wish to have the results of broad observations and general impressions reinforced or corrected by minute and careful investigation, will find in *Children's Sleep*,¹ by Professor S. RENSCHAW, associated with Vernon L. Miller and Dr. Dorothy Marquis, who are research Fellows under the Payne Fund, the account and conclusions of such an investigation. Of course, there are a chairman, a committee, and a dedication as well. The research was concerned with a group of children of both sexes between the ages of 6 and 18 years. The main criterion was the degree of mobility during sleep. This was ingeniously measured and recorded so as to ascertain a normal, and to assess any variations from the normal produced by the ingestion of coffee and by the watching of motion pictures of several types. The conclusions do not appear to be strikingly helpful, and the steps taken to arrive at them are set out with a superabundance of detail, and with what must be to many a tedious meticulousness. By some they may be regarded as significant and interesting.

The discovery of the lymphatic system and the demonstration of the chyliferous vessels were the work of a number of seventeenth century physiologists. Aselli of Cremona discovered the lacteals in 1622, and twenty-eight years later OLAUS RUDBECK of Upsala published a *Nova Exercitatio Anatomica*, in which he demonstrated the existence of vessels containing clear lymph.² An Englishman, Jolyffe, had described similar vessels ten years earlier in a Cambridge thesis. In commemoration of the tercentenary of Rudbeck's discovery, Messrs. Almqvist and Wiksells of Upsala have published a facsimile of the *Exercitatio*,³ with its two fine plates, for the Medical Faculty of Upsala, of which Rudbeck was a member. Rudbeck was professor of botany at Upsala, as well as of anatomy, and his name is probably better known as the godfather of the genus *Rudbeckia* even than as a physiologist. The daisy-like composites known as *Rudbeckia* are now familiar to all gardeners.

² *Nova Exercitatio Anatomica, Exhibens Ductus Lymphaticos, et Vas Glanularum Serosa*. By Olaus Rudbeck. Upsala: Almqvist and Wiksells.

The Frenchman who asked an English colleague "Qui est ce Monsieur Pink?" will find an adequate answer in a little book by Dr. Ch. Rocaz of Bordeaux, which has been translated into English under the title of *Pink Disease* by Dr. I. J. Wood. Although the malady is known in France as "infantile acrodynia" the translator has wisely adopted the title more commonly used in the English-speaking countries, and he has also incorporated a certain number of recent observations to bring the book up to date. A bibliography of ten pages shows the extent to which the literature on this comparatively newly recognized disease has been studied, and the result is a thoroughly readable, well-balanced little volume. A historical review leads on to a section on aetiology, and there follow over seventy pages on symptomatology, this forming the bulk of the book, and well illustrating the diversity of types in which the disease occurs. The author sums up the views on pathogenesis, and favours the conception of an inflammation of the nervous system closely related to epidemic encephalitis. The English version runs smoothly, and is welcome as a concise exposition on this subject.

In a pamphlet of twenty-seven pages Dr. GIUSEPPE BERTINI¹⁰ of Faenza maintains that the opinion held by some writers of the rarity of osteomyelitic infection in the newborn and sucklings is erroneous, and he gives details of eleven cases in support of his view. Of these seven were staphylococci, three streptococci, and one diplococcus. Vaccines may help, but surgical intervention offers the best hope in this very fatal disease of early infancy. The author appends a useful bibliography.

Preparations and Appliances

RADIUM-HOLDING FORCEPS AND RADIUM STERILIZING TRAY

DR. WILLIAM TENNENT (radium officer, Glasgow Royal Infirmary) writes:

The radium-holding forceps illustrated herewith were designed to overcome some of the defects inherent in the types previously employed, and are intended for use in the handling of radium needles and tubes, and in threading needles either before or after sterilization. The usual dissecting type of forceps, even when fitted with a special jaw,

is unsatisfactory for handling radium, as the fingers must be brought within an inch or so of the jaw if sufficient pressure is to be applied to prevent the needle swivelling during threading. Where large quantities of radium are being repeatedly handled and threaded each day this constant proximity of the fingers to the radium is not without risk, but in the forceps illustrated the radium is constantly kept at a fixed distance of six inches from the hand. The jaw is diamond-shaped in cross-section, and holds firmly all

needles with a screenage of 0.5 mm. to 1 mm. platinum, while the elongation of the jaws prevents the large needles from sliding laterally while being threaded. The forceps are provided with a sliding lock for use during threading, and this serves to relieve the strain on the fingers when large numbers of needles are being dealt with.

The use of the radium sterilizing tray illustrated has been found to facilitate the handling of threaded radium needles

in the operating theatre. The instrument consists of a stainless steel back-plate, to which is fitted a lead block drilled vertically with several rows of openings passing the whole length of the block, and into which the radium needles may be inserted. The lead block is held in position by a stainless steel band, screwed into the back-plate. The needles, having been threaded in a radium bench, are inserted into the openings in the lead block and firmly held in position by having the threads clamped against the back-plate. The fully charged sterilizing trays, which measure only 9 by 10 cm., may now be placed in a lead-lined carrying box and taken to the operating theatre. These trays have the advantage over the usual type in that there are no movable parts in which the needles may become fixed and bent. In practice it has been found that even very small needles do not become dislodged from the lead block during sterilization, provided the threads have been securely clamped into place.

The forceps and tray have been made for me by Mr. Charles F. Thackray of Park Street, Leeds.

A CAUTERY AND LAMP UNIT

We have had the opportunity of seeing a demonstration of a portable unit for cautery and light, constructed, in one model, for use with either direct or alternating current, and in another, a smaller model, for alternating current only, at voltages of 100 to 130 and 200 to 250. It is also supplied, again for alternating current, in the form of cautery only and of light only. The unit has been put on the market by the Balding Electrical Company (33, Theobalds Road, W.C.1). The mechanism is earth-free, and it gives an excellent light for ear, nose, and throat work or other applications, while its value as a cautery appears equally evident. Everything has been done to make it as foolproof or mischance-proof as possible. The weight of the more ambitious instrument is 14 lb., and its size 9 by 7 by 6 inches, while the other, for alternating current supply only, is much smaller, and weighs only 3½ lb. A unit of this type, with the maximum of convenience and readiness of application, may be found very useful in general practice as well as in certain specialties. It is mounted in an ebonized mahogany case, and is chromium-plated.

ANTIVIRUS JELLY FOR CORYZA

Glaxo Laboratories (56, Osnaburgh Street, N.W.1) are now marketing a new antiviral preparation intended for the treatment of the common cold. Antiviral nasal jelly is stated to consist of sterile detoxicated filtrates from cultures of *B. pneumoniae* (of Friedländer), *M. catarrhalis*, and mixed streptococci, incorporated in a glycerin base, together with 1 per cent. of ephedrine. Its viscosity is such as to bring the jelly into intimate contact with the folds of the nasopharyngeal mucous membrane. It is sold in collapsible large-nozzle tubes at 1s. 6d.

THE LARGEST MUNICIPAL HOSPITAL ORGANIZATION IN THE WORLD

The section of the annual report of the London County Council for 1932 dealing with hospitals and general medical services¹ is belated, but much is to be forgiven when one contemplates the mass of tabulated information embodied in the document. Even though five years have passed since the Local Government Act whereby a large number of hospitals were transferred to the Council from other authorities, many otherwise well-informed Londoners have no idea how vast a hospital population the Council accommodates. In its general and special hospitals, including the sick-beds in the public health and public assistance institutions, there were 35,000 patients on the last day of the year which the report reviews, and during that same year 260,000 people—equal to the total population of Cambridge—had been admitted. This number includes 10,500 infants born in hospital. The demand on the Council's maternity accommodation increases by about 1,000 cases a year. The attendances at the ante-natal clinics, numbering 48,618 in this year, are also multiplying with great strides.

GENERAL HOSPITALS

In the L.C.C. general hospitals 80 per cent. of the beds, on the average, are occupied, and the average duration of stay is thirty-eight days. In some of these institutions units have been established for branches of medicine and surgery which are of such a specialized nature that it is not convenient or economical to establish a unit for them at every hospital. These include plastic surgery, radium therapy, rheumatism, thoracic surgery, thyroid diseases, and lupus. Further special arrangements were made during the year for research work to be carried out in the treatment of lobar pneumonia by anti-pneumococcal serum. Some indication may be gathered as to the work of these hospitals from the fact that during the year under review 28,490 administrations of general anaesthetics were made; 22,757 patients were treated in the physiotherapeutic departments; and diagnostic x-ray work was done on behalf of 56,182. The number of new patients attending the out-patient departments was 62,157—a very minor figure, of course, compared with the corresponding one for the London voluntary hospitals.

INFECTIOUS FEVER HOSPITALS

The superintendents of the infectious diseases hospitals give accounts of research and other work, including the serum treatment of cerebro-spinal meningitis and the drug treatment of chronic encephalitis. It is mentioned that observation into juvenile behaviour disorders following encephalitis lethargica and those of the ordinary "difficult child," where no history of encephalitis lethargica can be found, has shown that there is a marked similarity in the two cases, and the opinion has been expressed that both are due to organic causes. The practical value of hypodermic injections of bulbocapnine in the subduing of outbreaks of misbehaviour has been confirmed, and so far no other drug has been found to be so efficacious. The prophylactic inoculation of nurses against diphtheria has been continued. In the course of this work at the North-Western Hospital certain observations on the antigenic value of alum toxoid have been completed, and a commencement has been made with similar observations with regard to ferriol toxoid. The immunizing value of these prophylactics now seems to have reached a high

degree of efficiency, and no nurse has required to go off duty as a result of the inoculations. A complete pathological service, with group and single institution laboratories, is on its way to completion. In 1932 the total number of pathological examinations carried out for the Council's general hospitals was 131,941. In the fever hospitals the laboratory work consists mainly of investigations in connexion with the diagnosis and treatment of diphtheria, and 104,102 microscopical examinations of Löffler serum cultures were made during the year.

DISTRICT MEDICAL SERVICES

The district medical services are also covered in this report. Part-time practitioners in these services paid 47,776 domiciliary visits, and medical officers on the staffs of hospitals 22,490. It appears that in London, owing to the effective co-operation between the district medical and the district nursing services, there is some reversal of the usual tendency to seek hospital accommodation in sickness. The services of district nurses in reporting on the suitability of patients' homes for home nursing have been of much assistance, especially in regard to patients in receipt of relief but not attended by the Council's doctors. Under the new conditions, now that the district medical and nursing services are an integral part of the whole administrative scheme for the care of the sick, more demand is being made for nursing in the home. District medical officers have been quick to take advantage of the nursing facilities at their disposal, and it seems that a real need is being met. The considerable saving in hospital expenditure is to be set off against the expense of the district service.

LONDON AMBULANCE SERVICE

The labours of the statistician afford us a glimpse of the activities of the London ambulance service, which is now in two parts: one for accidents and the other for general cases. The number of times the ambulances were called out in the accident service in 1932 was 42,672, a figure below that of the previous three years. The figure for 1933, with the steep rise in the curve of traffic accidents, must be expected to show an increase. The hours of the day in which the largest number of ambulance calls are made are from 3 p.m. to 7 p.m. From 8 a.m. to midnight the hour of fewest calls is the first hour. Saturday is the day of the week which makes the greatest demand on the ambulance service, and Friday comes next. The busiest months of the year are July and August, and the quietest are February and January. The average time taken by an ambulance to reach the case is six and a half minutes, and to reach hospital fourteen and a half minutes. We will permit ourselves one final figure: the total staff of the Council's hospital, laboratory, district medical, and ambulance service, including whole-time and part-time officers, numbers 18,842 persons.

S. Ganot (*Thèse de Paris*, 1933, No. 582) states that, during the period 1930-2, the number of cases of recent syphilitic infection observed at the Hôpital Saint Louis and the various dispensaries of the French League against Venereal Disease in Paris amounted to 739 cases in 1930, 722 in 1931, and 572 in 1932, so that diminution in the incidence of syphilis in Paris amounted to 30 per cent. The Paris district, however, was the only one in France where this diminution was observed, as at a congress in Strasbourg in 1933 attention was called to the endemic increase of syphilis in France. The decline of syphilis in Paris is attributed by Ganot to several factors—namely, the results of propaganda against venereal disease, the education of doctors and patients, and the economic crisis, which is said to favour sexual abstinence.

MEDICAL RESEARCH IN THE MALAY STATES

The annual report for 1932 of Dr. A. Neave Kingsbury, director of the Institute for Medical Research, Kuala Lumpur, contains the notification that in order to assist State medical authorities in times of epidemics of enteric fever, cholera, or plague a mobile unit including a traveling laboratory will now be available. Primarily intended for purposes of diagnosis, this unit will also render assistance in control measures, so far as may be possible. As in previous years the work of the Institute has covered a wide field despite financial restrictions. Some of the more important lines pursued are as follows.

PROPHYLAXIS AGAINST MALARIA

In the previous report it was noted that an investigation of the prophylactic value of quino-plasmoquine had shown its value, though problems of toxicity were encountered, and the cost of the procedure was considerable—a serious handicap to undertaking such protection on a large scale. Atebrin for treatment was also mentioned as being well tolerated in curative doses, and superior to quino-plasmoquine in preventing relapses. Dr. R. Green has continued research in this connexion, and the present report records the results achieved. One series of 125 cases of malaria of all types was treated with atebrin, and another series with quino-plasmoquine. It was found that the action of atebrin was swifter, but this drug is not available in a form suitable for injections, and is therefore not applicable to cases of cerebral malaria and persistent vomiting. Its use is at present limited in cases of subtertian malaria to patients who can retain and absorb it when given by mouth. Like quinine, atebrin does not affect the viability of the gametocytes of *P. vivax* or *P. falciparum*, but, when administered for seven days or even less, the gametocytes of *P. vivax* are destroyed with sufficient rapidity to prevent the infection of anophelines. As regards gametocyte carriers of *P. falciparum*, neither atebrin nor quinine is effective in preventing the infection of mosquitos having access to such patients when under treatment. But, since atebrin is definitely the more effective in preventing relapses in all three types of infection, the production of further generations of gametocytes (on relapse) is less likely to occur among cases so treated, and thus atebrin possesses greater prophylactic value than does quinine, especially as it appears to be less toxic.

A series of experiments was commenced on rubber estates to discover whether the employment of atebrin would diminish malarial incidence and transmission if restricted to fertile individuals and not distributed for mass treatment—a much more costly method. The investigation was complicated by the fact that estates vary, some relying mainly on oiling while others are on a "care and maintenance" basis, oiling having been suspended or limited. In still other instances the managements are unable to afford the adequate supervision, labour, and material necessary for the continued maintenance of an effective oiling campaign. Although everything possible in regard to antilarval measures is being done on the majority of estates, there is a growing tendency to place reliance on the quinine treatment of individuals. This restricts the general severity of the disease, but the frequency of transmission by anophelines, and the actual incidence of malarial infections are little affected. It has been proved on many occasions that quinine, given in amounts less than the curative dose, fails to prevent the onset of malaria after a person has been bitten by infected mosquitos. This involves the administration to labourers of large doses of quinine, with consequent cinchonism, or dependence on inadequate dosage. In such circumstances the possibility of atebrin seemed hopeful, and three estates were accordingly tested, 450 persons being treated with it, and 353 serving as controls. The experiment was in progress at the time of preparing the annual report, but the preliminary figures indicated a very marked relative fall in both spleen and parasite rates in the case of those treated with atebrin. Examination is also being conducted of the new cinchona product "totaquina," recommended by the Malaria Commission of the League of Nations. The preparation was well tolerated in doses above clinical requirements, but as yet there is no definite intimation that it is superior to quinine.

OTHER MALARIA INVESTIGATIONS

Cultural methods as a diagnostic aid have been explored by Dr. J. W. Field, who has employed the modification of Bass's technique suggested by J. G. and D. Thomson. No evidence has yet been obtained which suggests any diagnostic advantage of the cultural method over the usual thick blood film in benign tertian and quartan infections. No strain was encountered with such early sporulation as to suggest a twenty-four-hour cycle. There was great variety in the vigour of growth, which could not be correlated with the severity or chronicity of the infection, though an interesting finding was that a relatively high proportion of successful cultures were obtained from patients with marked splenic enlargement. The results of the larva surveys so far lend little support to the theory of inverse larval and adult density. On the contrary, there was a surprisingly close correlation for several species between the larval findings and the adult catches. In one area, oil which had been used for larvicidal purposes was collected, and used again under control. It was found that its lethal power had diminished from 70 per cent. to 25 per cent., and the conclusion was established that the repeated use of antimalarial oil must be condemned. Other experiments showed that the oiling of water had little or no effect on the health of poultry.

TROPICAL TYPHUS

During the period under review there was an apparent fall in the number of cases of "K" type tropical typhus, and also a continued decrease in the "W" type cases. Evidence was obtained that there is a marked rise in incidence in the month of December, which continues during January and recurs in July. It has been suggested by Dutch workers that "K" type tropical typhus and Japanese river fever are essentially the same disease. Work in connexion with the Institute indicates that the two diseases are immunologically identical. An analysis of 529 cases of typhus showed that it is in the main a disease of adults. As regards sex incidence, the distribution of the "K" type cases was 100 males to twenty-seven females, and of the "W" type 100 to fifteen.

A statistical inquiry indicated that Indians suffered unduly from enteric fever, while Malays were relatively free. A partly successful attempt was made to treat lepers by desensitization, extracts of proteose from the urine being applied to scarified skin areas. Rats fed on a vitamin-deficient diet proved to be no less resistant to leprosy than were others on normal diets. The control of quinine therapy by testing the urine for this alkaloid was found to be better secured by using Tanret's acid reagent as well as Mayer's, since the former will invariably precipitate quinine, while the latter does not always do so. Tanret's reagent invariably precipitates albumin, and thus it is necessary to ensure that the urine is albumin-free. Mayer's reagent only precipitates quinine in high dilution when the urine is acid enough.

ROYAL MEDICAL BENEVOLENT FUND

At a recent meeting the committee of the Royal Medical Benevolent Fund voted eighty-eight grants, amounting to £1,971. Subscriptions and donations are very urgently needed in order that the activities of the Fund may be maintained. Legacies are needed to support the annuity department. Cheques should be made payable to the honorary treasurer, Royal Medical Benevolent Fund, 11, Chandos Street, Cavendish Square, W.1.

The following are particulars of a few cases helped.

M.D., aged 82, widower, has been in practice as long as his age and infirmity permitted. He is now confined to his bedroom, living in very straitened circumstances, indeed practically destitute. He has no relatives who can give financial help. Income, which includes old age pension, approximately £48. Fund voted £40.

Widow, aged 77, of M.R.C.S. Her husband had retired and was on pension, which ceased at his death; she was left with private means of £20. Another charity has made a grant of £30. Fund voted £13 for six months pending application for old age pension.

Widow, aged 64, of M.B., C.M. On her husband's death in 1924 she served as housekeeper in a nurses' home for some years until failing health compelled her to relinquish the post. She is suffering from cardiac enlargement. National health insurance provides £1 4s a month, letting room £1 a month, and friends have given £15. Fund voted £26.

British Medical Journal

SATURDAY, FEBRUARY 24th, 1934

A MILK RATION FOR CHILDREN

At a meeting of the Children's Minimum Committee, held at the House of Commons on February 15th, the proposal was advanced that "a daily ration of fresh milk should be made available for all children attending State-aided schools and for younger children through the Public Health Department." Though no actual resolution was put to the meeting, all present were invited to support the committee in urging the Government to give effect to this recommendation. The term "fresh milk" is a little ambiguous. It might mean the opposite to canned milk. On the other hand, it might mean raw as opposed to heat-treated milk. Sir Ernest Graham-Little, M.P., moved that the word "fresh" should be deleted and replaced by the words "pasteurized at a low temperature." This amendment was not accepted, and it would therefore appear that the term "fresh milk" is to be regarded largely as synonymous with raw milk.

The issue is more important than may appear at first sight. Numerous investigations, of which we may quote that recorded by Corry Mann, and the large-scale experiment carried out in Lanarkshire under the auspices of the Scottish Board of Health, have shown the undoubted value of a daily ration of milk in the growth and development of young children. In both of these investigations the children in the groups receiving extra milk showed at the end of a few months a marked superiority in height and weight over the children in the control groups. There is therefore every reason to believe that a daily ration of milk given to children, particularly to those who are living on the borderline of undernourishment, is likely to exert a beneficial action on their mental and physical development. Before giving, however, its approval to the recommendation of the Children's Minimum Committee, the medical profession will do well to pause and enter a caveat. Raw milk, as laboratory examinations in various parts of the country have firmly established, is frequently infected, either from the cow or from human carriers, with micro-organisms that are pathogenic to man. The most authoritative figures reveal an infection of 6.7 per cent. of samples of raw market milk with living virulent tubercle bacilli and of 20 to 30 per cent. with *Brucella abortus*. Besides these two organisms, it is known that milk becomes infected from time to time with haemolytic streptococci, diphtheria bacilli, and members of the typhoid, paratyphoid, food-poisoning, and dysentery groups. The attitude of those who would minimize the importance of these organisms in milk is not easy to comprehend. According to the report of the special committee appointed by the People's League of Health to make

a survey of tuberculosis of bovine origin in Great Britain, it is estimated: (a) that about 6 per cent. of all deaths from tuberculosis are caused by the bovine type of bacillus; (b) that about 2,000 deaths, mostly in children, occur annually from this cause; (c) that at least 4,000 fresh cases of bovine infection develop each year; and (d) that an immense amount of suffering, invalidity, and often permanent deformity is caused by this bacillus. These estimates, it may be noted, were worked out with great care from the Registrar-General's returns, and err, if anything, on the low side. Tuberculosis, however, is not the only milk-borne disease. Undulant fever, caused by *Br. abortus*, is being reported now from many parts of the country, and is not by any means confined to adults. The devastating effect of pathogenic strains of haemolytic streptococci, as revealed in the recent outbreak in a South Coast pleasure resort, where the consumption of an infected milk supply led to over 1,200 primary cases of septic sore throat with sixty-five deaths, will be fresh in the minds of many public health workers. The outbreak of paratyphoid fever at Epping in 1931, involving 312 cases with eight deaths, will likewise be remembered. But what further need is there to labour the point? That a large amount of disease is carried by raw milk is no longer an opinion; it is a fact—a fact as well attested as any in the domain of medical science. The recommendation, therefore, that milk should be consumed in the raw state is equivalent to the support of a measure which must result in the occurrence of sickness and death among a proportion of those affected by it.

The alternative to raw milk is not no milk, but milk rendered safe by some form of heat treatment. Of the various forms available low-temperature pasteurization appears to be the most satisfactory. As carried out in modern plant of proper design and with automatic temperature control, it can be trusted to destroy the various pathogenic organisms that have been mentioned. The objection sometimes raised by the protagonists of raw milk that pasteurization diminishes the nutritive value of the milk is based on very insecure evidence. Stirling and Blackwood of the Hannah Dairy Research Institute, in their monograph on "The Nutritive Properties of Milk in Relation to Pasteurization," after a very thorough review of the literature, come to the following conclusions: "... there do not appear to be any good grounds for the belief that pasteurized milk is a less valuable component of the diet than raw milk for children who satisfy the bulk of their nutritive requirements from sources other than milk." And again: "There are, therefore, strong grounds for the belief that infants can satisfy all their requirements on diets of adequate amounts of pasteurized milk provided that extra vitamin D, and, of course, vitamin C, are added to the diet." (Original in italics.)

Practical difficulties in the way of supplying children with properly pasteurized milk will be encountered in many towns and country districts. The alternative here is to see that the milk is boiled immediately before use. If these precautions are taken, all milk being rendered

safe either by pasteurization or by boiling, the Children's Minimum Committee is likely to receive very strong support from the medical profession. If, on the other hand, they are neglected, it must be the duty of every medical officer concerned in implementing the scheme to point out the grave results that are likely to follow the consumption of milk in the raw state.

BARBITURATES

Papers and reports and letters in the columns of the *British Medical Journal* and in those of our chief contemporary, together with much vapouring by the lay Press, have brought the barbituric acid group of hypnotics into the foreground once more. It is something of a paradox that sedative drugs should act as irritants to the medical profession, but for twenty years or so veronal and its congeners, under many names, plain or fancy, have been apt to provoke controversy. Thus in 1927 we had a long and lively correspondence on "drugs for sleeplessness," centring round the barbitone compounds; and now, in the *Lancet*, following a debate at the Royal Society of Medicine,¹ Sir William Willcox on the one side, and Sir Maurice Craig and those who think with him on the other, have joined issue again in "the battle of the barbiturates."

In our opening pages this week will be found an address by Dr. Mutch on proprietary remedies, with special reference to hypnotics. We print also Dr. Featherstone's paper on the use and misuse of basal anaesthetics, and a warning by Mr. McNeill Love, founded on two fatalities after the use of basal narcotics. Again, at page 331, Dr. Robert Richards puts on record a symptom (he calls it "automatism" for short) observed by him in accidental poisoning by barbitone derivatives. In the *Lancet* of February 17th Dr. R. D. Gillespie has expanded, with very full references to the literature, his contribution to the December debate, heading this, "On the Alleged Dangers of the Barbiturates." The full text of Sir William Willcox's opening paper, to which Dr. Gillespie's article is largely a rejoinder, will be in our readers' hands a fortnight hence. A mass of information and of opinion is thus accumulating, from which in due course a considered judgement may emerge, and even a working policy. The difficulty at the moment is that during a discussion in which views are sharply opposed it is hard to distinguish between evidence and advocacy. We have heard it said that as a topic the barbiturates, like milk, are always on the point of boiling over. But while it would be premature to attempt a summing up at this stage, we venture to offer a few interim reflections in the hope of clearing the issue and perhaps of cooling the atmosphere. We shall not touch here upon the barbiturates and kindred drugs in basal anaesthesia.

There are, fortunately, several points on which all are agreed. The first is that these drugs need thought

and care in their administration. They should be supplied only on the order of a qualified practitioner. It is altogether wrong (as Dr. Nesbitt-Wood wrote the other day) that in defiance of the law "a number of lesser chemists are prepared to sell them over the counter like so many sweets." Casual self-medication must be discountenanced; but, on the other hand, medical men should not be hampered in the prescription of sedatives for appropriate cases by irksome regulations made merely in response to a popular demand. So far as we can judge, the general opinion of the profession to-day, with one notable dissentient, is that the barbiturates, or some of them, have a place, and a valuable one, in the practice of medicine. It is also widely held that some further restriction upon their purchase by the public would be desirable from every point of view. If, as seems likely, amending legislation for control of the sale of hypnotics is under consideration by the Poisons Board set up under the Pharmacy and Poisons Act of 1933, we may feel sure that in recommending any new procedure to lessen the risks of poisoning, whether accidental or suicidal, from the misuse of barbiturates, the Board will pay due regard to the weight of medical opinion and to the need for interfering as little as possible with the freedom of medical practice.

For the prescriber, as Dr. Mutch says, the point of practical importance with the barbitone group is the margin of safety between the hypnotic dose and the lethal one. This margin varies a great deal, and is dangerously narrow in some members of the series. It is therefore a good working plan to prescribe only a hypnotic whose action is well known, and to keep the total quantity ordered at any one time well below the recognized fatal dose. Again, the prescription by rule of thumb of barbiturates in combination with coal-tar analgesics such as amidopyrine seems open to objection. Sir Maurice Craig has long held that whereas some doctors prescribe hypnotics before they are really necessary, at least as much harm is done by not giving hypnotics early enough. At the Brighton Meeting of the British Medical Association in 1913 he mentioned four abuses of these drugs: (1) the prescribing of hypnotics by patients themselves, (2) the use of the wrong class of drugs; (3) the increase of the dose to a poisonous extent in the endeavour to obtain sleep when the usual medicinal dose has proved ineffective; (4) leaving a patient on some hypnotic night after night without bearing in mind the effect that the drug might be having on the patient. A very large number of new derivatives of barbitone have been discovered since then and placed on the market, and they are now perhaps the most commonly used of all drugs for sleeplessness. The sales of, for example, medinal (sodium barbitone) and of dial (diallyl barbituric acid) must be enormous. Though a great deal has been learnt about hypnotics in general and barbiturates in particular during the past twenty years, we doubt whether Sir Maurice Craig's four "don'ts" need much amendment to-day.

¹ *British Medical Journal*, December 30th, 1933, p. 1213.

DISSECTING ANEURYSM

The current theory of the causation of dissecting aneurysm as found in even the best textbooks on pathology, which refers the condition mainly to external violence or atheroma, is very far from the truth. The matter has recently been examined thoroughly by Professor Theodore Shennan of Aberdeen, the results of his investigations appearing in a monograph on dissecting aneurysm included by the Medical Research Council in its Special Report Series.¹ Professor Shennan has personally examined twenty-eight cases and has analysed nearly three hundred from the literature, and as regards the above-named factors he finds that they seldom figure in the aetiology. External violence tends to produce complete, rather than incomplete, rupture of the vessel wall, and it can be excluded in the great majority of cases of dissecting aneurysm; it is mentioned in a few cases only. As regards atheroma, this, being a relatively common condition, is often found associated with dissecting aneurysm, but in only six out of 218 cases of recent rupture with dissection has this been definitely attributed to it. It is generally accepted that syphilitic aortitis is a less frequent cause of dissecting than of sacular aneurysms, and Professor Shennan's figures confirm this view; he gives 10 per cent. as the maximum incidence, although the diagnosis in some of the cases appears to be doubtful. The most important predisposing factors in the production of dissecting aneurysm are, according to the author's observations, primary degenerations of the middle coat of the aorta. These are known to occur as the result of various toxic conditions, among which are mentioned gout, diabetes, typhoid fever, diphtheria, scarlet fever, measles, influenza, and other infections. They include fatty and atrophic changes in the muscle, frequently with complete disappearance of the fibres in small areas of the wall; hyaline and mucoid degeneration of the connective tissue; swelling, varicosity, and fragmentation of the elastic laminae, and the development of "faults" in the middle coat. Weakening of the vessel wall by these changes may be of such a degree that rupture occurs under the influence of apparently normal blood pressure, as when it happens during sleep. The author's analysis shows, however, that in the majority of cases the direct cause of rupture is some actual physical strain, such as occurs in severe muscular exertion, hurrying to appointments, defaecation, mounting stairs, even slight strains such as sitting up in bed. In four cases the rupture occurred in a fit of passion, and five cases were epileptic. The degenerations are mostly generalized throughout the vessel, and consequently the prevalence of the ascending aorta as the usual site of rupture would appear to be determined mainly by mechanical factors. The author believes that the abrupt diastolic recoil meeting the resistance of the closed aortic valve is of greater importance as a factor in producing the primary tear than an increased systolic blood pressure. Professor Shennan's monograph is not confined to the matters referred to above, but deals with the subject of dissecting aneurysm in all its aspects, including the symptoms and clinical signs, and it will be of much value not only to pathologists, but also to clinicians who may encounter the condition during life.

VITAMIN C IN ARCTIC BERRIES

Professor Göthlin of the University of Upsala has recently reported² the results of an extensive research into the antiscorbutic properties of Arctic berries. Scurvy is a definite menace in northern latitudes, owing to the long period during which local supplies of green vegetables and fruits are unobtainable. In the eighteenth century scurvy was a common complaint in Scotland at the end of each winter, and it apparently still constitutes a problem in the northern parts of Sweden. The genesis of the present investigation was the report from physicians in the Norrland district that diets deficient in vitamins probably accounted for the undue frequency of certain diseases. Göthlin concluded that nearly 20 per cent. of the school children in certain districts suffered from vitamin C deficiency in the early spring. Searching for the possible local sources of antiscorbutics, he found that black currants, raspberries, and cloudbberries were all effective antiscorbutics, and that a considerable proportion of their activity was retained when they were preserved. Cloudberry juice in particular was found to be nearly as effective an antiscorbutic as orange juice. Other berries were much less potent; for example, whortleberries were found to have very little antiscorbutic action. The cloudberry plant (*Rubus chamaemorus*) grows in this country, but it is not well known, for it is only common in the Highlands at levels above 2,000 feet. Apparently it grows abundantly in certain areas in the Norrland, and Göthlin suggests that the picking and preserving of cloudbberries ought to be organized in order to provide an adequate local supply of antiscorbutics, which would save the cost of importing oranges.

CHILD GUIDANCE IN AMERICA

The child guidance movement began in America, and its development in that country will largely influence its development here. The position of the child guidance clinic in the United States is at present, according to Dr. D. N. Hardcastle,³ not at all clear-cut. Its work is somewhat nebulous, and is undergoing constant and rapid change. The lines of approach and goals of treatment are by no means stabilized, the focus of attention shifting from the child itself to the environment, and in the environment from the school to the parents, according to the way of thinking of the clinic in question. This way of thinking may itself change completely in a comparatively short time. In order to gather some information on the probable direction of child guidance work in the future Dr. Hardcastle circulated a questionnaire to twelve representative American clinics. His first question dealt with the services which the general practitioner can render to the clinic. The majority of replies complained that the general practitioner's lack of psychiatric education makes him unable to co-operate, but five clinics out of twelve report favourably on his sending of cases to the clinic and his value in looking after the physical side of the patients. Three clinics consider that, when adequately trained, he should treat the bulk of the patients who now come to the clinic; and one clinic records the close, all-round co-operation of

¹ No. 143. London: H.M. Stationery Office, 1934. (2s. 6d. net.)

² *Acta Med. Scand.*, 1933, Supplementum 53.
³ *Brit. Journ. Med. Psychol.*, 1933, xiii, 328.

medical practitioners. On the other hand, another clinic regards itself as in opposition to the medical practitioners, and three comment on the interest and co-operation of paediatricians in contradistinction to the apathy of the family doctors. Eleven clinics state that cases should be referred from all sources and not only medical ones; three stress the importance of medical references, and two will not treat cases until the general practitioner in charge has been informed and has given permission. In reply to Dr. Hardcastle's suggested criticism that the child is subjected to such a team of people that he becomes merely the hub of the complicated machinery of the clinic, eight clinics emphasize the very close personal contact which the child has with the psychiatrist, a closer contact than is obtained under any other conditions of medical treatment, for the parents are not involved, being dealt with by the social worker. Four replies consider that with the younger group of children the parents should often be the central point in treatment, the child's behaviour being regarded, until treatment has reached a certain point, as purely symptomatic. The typical reply concerning the aim of the clinic is that in the first place an attempt is made to evaluate the child's difficulties as within the child and as purely environmental, or as a combination of both. The general aim of treatment is to create in the clinic such a relationship with child and parents as to enable them freely to bring up the problems bothering them and to get a clear idea of their feelings about these and each other. The clinic will then make some attempt to remedy environmental defects and to give the school a better understanding of the situation. Correction follows rather as the outcome of this clarification of feelings and attitudes than as a result of success in attaining a specific goal. The technique employed is chiefly that which will suit the child; full use is made of psycho-analytic knowledge, but psycho-analysis is only practised by one clinic on a small group of selected children. All the facilities available at the clinic are employed to create a friendly feeling with the child. Play is used wherever possible with the younger group, and free conversation with the older group. Question and answer and re-education methods form part of the treatment. The director of a large clinic, who had the opportunity of criticizing these replies, declared to Dr. Hardcastle that the more progressive clinics had evolved a much more flexible and elastic approach during the last year or so. His own clinic was more and more tending to simplify its treatment and avoid unnecessary multiplicity of contacts with clinic workers, the team approach only being used when a full investigation could help that treatment. He strongly deprecated the attitude that any contact with the patient had to take a definite form in order to fit in with the set clinic procedure, and that clinic workers should have to conform, in dealing with the situation, to recognized clinic machinery. He also said that a much freer attitude towards treatment had been developed: after the first interview, when the patient had been shown what the clinic could offer, the responsibility for having treatment or not was shifted wherever possible to the parent. Patients should, he said, be encouraged to attend the clinic rather than be visited by the social worker in their homes.

PROGRESS WITH HEARING AIDS

In recent years, as Mr. Douglas G. Carruthers indicates in an interesting article,¹ a great effort has been made to put artificial hearing aids on a more scientific basis. The otologist, finding the difficulties of this task beyond his unaided powers, has invited the co-operation of the engineer, the physiologist, and others. The result of their combined efforts has thrown a new light on the question of hearing aids, and it is now possible to prescribe an apparatus which coincides in performance curve with the patient's hearing loss at varying frequencies as measured by an audiometric test. Coincidentally with this, the National Institute for the Deaf, under whose auspices much of the work has proceeded, has been active in its own endeavours to protect the public from falling victims to the vendors of some of the advertised hearing aids on the market. Mr. Carruthers mentions the work done in the Department of Industrial Physiology of the London School of Hygiene and Tropical Medicine on hard and soft carbons, and refers to this as only a rudimentary advance. Out of these early experiments, however, great progress has been made. Much attention has been given to the production of suitable carbons—a matter of considerable difficulty and importance—and investigators are now concentrating on hard, medium, and soft carbons, both large and small, which, when used in conjunction with receiver diaphragms of a correct residual frequency, may be found to yield the response peaks most nearly suitable to a patient's audiometric response curve. The General Post Office Research Laboratories have played an important part in determining these response curves, and it is now possible to define the frequencies picked up and amplified by various instruments as a guide to prescription. There is still much more work to be done along these lines, and room for further improvement. In other laboratories investigations are being conducted with wireless equipment, etc. Carbons are not used here, but valves, special tone control transformers, volume control, etc., are the rule, and the loud-speaker becomes the microphone when used as a deaf aid. These instruments give a clear and powerful reproduction, but are naturally not portable. An effort is being made by certain investigators working upon this class of instrument to overcome this problem, and to produce a portable instrument which gives an equally good reproduction. We understand that the difficulties are on the point of solution, in which case a very notable advance will have been made. All these instruments find their greatest usefulness in cases of deafness with a sound nerve. When the nerve is affected, the most suitable form of aid still seems to be the mechanical—for example, speaking-tube, trumpet, etc.—while lip-reading will of course always hold its place as the greatest aid the deaf can have. With regard to re-educational methods, though some otologists claim excellent results from the use of the electrophonoids of Zünd-Burguet, others give less encouraging reports, stating that while nearly all types of deafness improve to a greater or less degree—including cases of nerve deafness—the vast majority of them fall back and lose within a few months most

¹ *Med. Journ. Australia*, 1933, ii, 342.

and in some instances all, of what they have gained, a second course of treatment being as a rule not so effective as the first. It is comforting, however, to reflect that at last the question of artificial aids to hearing is engaging the serious attention of otologists and workers in pure and applied science, and to hope that the points so ably brought out by Mr. Carruthers as demanding the consideration of these investigators are now actually being dealt with.

LEAD IN CANNED SARDINES

A recent investigation on the occurrence of lead in canned sardines¹ provides an interesting example of an unusual form of food contamination. The chemical laboratories of Messrs. Lyons and Co. carry out routine examinations for metallic impurities on all foods which have been in contact with solder. Such analyses in respect of sardines showed that 88 per cent. of the samples contained less than 20 parts per million of lead, but that the remainder yielded larger quantities, and in one case 150 parts per million of lead were found. Examination of the tins revealed no obvious relation between the amount of exposed solder and the lead contamination. On investigation of the process of sardine packing it was found that the fish were cooked on metal grills, which were supposed to be made of tinned iron but which in some factories were in reality covered with soft solder. It was observed that contact of the fish with such grills resulted in a serious contamination with lead. The maximum daily quantity of sardines that anyone is likely to consume is so small that lead poisoning from this cause would be a great rarity, but the investigation is of interest because it illustrates the unexpected channels through which food contamination may occur.

NUTRITIONAL NIGHT-BLINDNESS

Drs. Wilbur and Eusterman² of the Mayo Clinic record a most unusual case of night-blindness due to short circuit of the intestines. They remark that hemeralopia was recognized in the time of Hippocrates, and that liver or liver and honey was a cure for it. Recent experimental work has demonstrated that the symptom may be produced by faulty nutrition, particularly deficiency in vitamin A. Although functional hemeralopia is not uncommon in the Orient and some European countries, it is thought to be extremely rare in the United States. The patient was a man aged 48, a civil engineer. In 1904 he had symptoms of duodenal ulcer for which gastro-enterostomy was performed at the Clinic in 1919. In 1929 he had symptoms of jejunal ulceration, and two years later a gastrocolic fistula appeared. From 1931 to 1932 he had a good diet, but he suffered from diarrhoea, passing daily many liquid stools. On admission in 1933 he was in a cachectic state. The gastrocolic fistula was repaired, and all the symptoms ceased. The night-blindness began early in 1932. He noticed that the street lamps were yellow and dim, and being an engineer he blamed the local power plant, until he discovered the fault in his own eyes. He saw well in daylight, but at dusk he tumbled over things, ran into people, and fell down steps. His power of

light adaptation was very slow. The attacks were periodic, lasting from two to ten days, at intervals of one to four weeks. Since the repair of the fistula there has been no recurrence of the night-blindness. Nutritional night-blindness depends on a disturbance in the metabolism of the visual purple of the retinal red cells. In bright light the purple is bleached, but it is constantly being regenerated. Experiments have revealed a close relation between vitamin A and the visual purple. Friderica and others have demonstrated that there is a delay or failure of regeneration of the purple of animals deprived of vitamin A. Also Yudkin and others have shown that hog's retina has a high vitamin A content. It is thought that there may be a reversible reaction—vitamin A being needed for the production of the visual purple and the latter, under suitable conditions, producing vitamin A.

STANDING ADVISORY COMMITTEE ON PUBLIC HEALTH

The standing advisory committee which the Minister of Health proposes to set up to assist him in public health matters will consist of three representatives of the County Councils Association (the body which made the suggestion that such a committee should be appointed) and of the Association of Municipal Corporations, two of the London County Council, of the Urban District Councils Association, and of the Rural District Councils Association, and one of the Metropolitan Boroughs' Standing Joint Committee. The London County Council proposes to appoint as its representatives the chairman of its central Public Health Committee and its medical officer of health for the time being. The reference of the committee is: "To advise the Minister on any question of policy or administration affecting the public health services in England and Wales which may be referred to the committee by the Minister." The Permanent Secretary to the Ministry will act as chairman of the committee.

TREATMENT OF ADDISON'S DISEASE

The Therapeutic Trials Committee of the Medical Research Council is arranging an inquiry into the value of extracts of suprarenal cortex in the treatment of Addison's disease. The work will be done on the committee's behalf by Professor T. R. Elliott (University College Hospital, London), Dr. Robert Hutchison and Dr. S. Levy Simpson (London Hospital), Dr. J. F. Wilkinson (Royal Infirmary, Manchester), and Professor D. Murray Lyon (Royal Infirmary, Edinburgh). As it is desired to admit to these hospitals sufficient patients for the inquiry as soon as possible, the committee would be very grateful if consultants and practitioners having suitable cases of Addison's disease under their care would communicate with one or other of the physicians named above.

We regret to announce the death of Dr. A. H. N. Lewers, F.R.C.P., consulting obstetric physician to the London Hospital, and author of the well-known textbook on diseases of women which went through seven editions. We have to announce also the death of Mr. J. F. Dobson, F.R.C.S., who retired last October from the chair of surgery in the University of Leeds.

MARIE CURIE HOSPITAL

NEW X-RAY DEPARTMENT

The Duchess of York opened last week the new x-ray therapy department of the Marie Curie Hospital, Fitzjohn's Avenue, Hampstead. Her Royal Highness was welcomed to the borough by the Mayor of Hampstead, and to the institution by the Marquess of Reading and by Miss Maud Chadburn, the chairman of the Cancer Research Committee of the hospital. The French Ambassador and the Polish Minister were present, and Dr. Henry Coutard brought the congratulations of Professor Regaud; and of the Fondation Curie, Institut du Radium, l'Université de Paris. Miss CHADBURN reminded the company that during the last few years, the results having been tested by time, the importance of x-ray therapy had become more generally acknowledged. The Marie Curie Hospital had been working with radium with encouraging results—nearly every case taken in hand had been relieved, and it was hoped that a number had been cured, although that word was used with a proper hesitation until a sufficient number of years had elapsed without recurrence. The medical staff of the hospital, however, had increasingly felt that their results would be improved if the hospital could obtain a deep therapy x-ray plant to supplement the action of radium. The x rays would act in a similar manner to radium, but upon tissues which radium could not well reach. The opportunity arose of acquiring a house next door to the hospital, and here an apparatus had been installed which received the approval of the experts who had examined it. It was not always realized how costly such provision was—for example, the special windows in the cubicles for x-ray treatment cost £5 per square foot. The cost of the plant had been met by special gifts and bequeathments, but the maintenance of the new department, which included a ward for six patients and three single rooms for private patients, would add £2,000 a year to the maintenance cost of the hospital; and to find the means for pursuing the work had always been a problem since this medical women's venture was started. The MARQUESS OF READING added a few words testifying to the pride of those concerned at what had so far been accomplished at the Marie Curie Hospital. It was started originally as a clinic in 1925 by the London Association of the Medical Women's Federation, and later became a hospital; it had already treated over 2,000 cases of cancer in women with marked success. The DUCHESS OF YORK then declared the department open, and made an inspection of it. An expression of thanks to Her Royal Highness on behalf of the committee of management was conveyed by Mrs. WALTER RUNCIMAN.

X-RAY THERAPY OF CANCER

Miss HURDON took the chair at a special meeting organized by the medical committee of the Marie Curie Hospital on February 15th. Dr. COUTARD, who had come over to represent the Fondation Curie, Paris, at the opening of the new x-ray department at the hospital, delivered a lecture on principles of x-ray treatment of malignant disease.

Dr. Coutard said that he would consider first some results, secondly the technique, and lastly some general principles. Certain cases could undoubtedly be cured. His figures for the years 1921–6 revealed that 17 per cent. of forty-five patients with lymphosarcoma of the mouth and tongue had been alive and well after seven years; of forty-six patients with epithelioma of the tonsil and soft palate 28 per cent. had been alive after five years and 17 per cent. after seven years. The extra two years made little difference to cases of epithelioma of the larynx, as the figures for five- and seven-year survival in seventy-seven cases were 28 and 27 per cent. respectively. Some years would show much lower figures than the average and some would show higher.

Dr. Coutard said that he used constant potential machines with a voltage of 180 to 200 kV, a current of 4 mA, and a distance of 50 to 60 cm. through a filter of 2 mm. zinc, 3 mm. aluminium, and 1 cm. wood. The

depth dose for radio-sensitive tumours measured from 3,000 to 4,000 r, and for radio-resistant tumours from 4,000 to 5,000 r or possibly more. The biological results were radio-epithelitis and radio-epidermatitis in the mucous membrane and skin respectively, and these were exactly measured. The mucous membrane showed a complete destruction of the germinal layers and the appearance of a false membrane some thirteen or fourteen days after the first dose; this lesion was healed by the twenty-sixth day. The skin damage involved loss of the surface layers and denudation of the dermis; it appeared just as the mucous membrane lesion disappeared, and healed fifteen days later. To get the reaction in this form the dose must be spread over about fourteen days, two daily sessions of an hour being given. If a shorter time were taken over the same dose both skin and mucosal reactions appeared later and lasted longer, and the connective tissue might be involved. If the period were prolonged, for example to eighteen days, the reactions were much reduced in amount and delayed in appearance. Repair should be completed in the skin in about a fortnight, and there should be no scar. The radiologist might anticipate a good healing if the edges of the denuded area showed advancing islands of epithelial cells. There was an optimum dose for each variety of growth. If the dose was increased beyond a certain point the results got worse and not better. Two important factors were involved: the quantity of the dose and the duration of the treatment. For radio-sensitive undifferentiated tumours, such as lymphosarcoma, the important element was the quantity, the duration being of less significance. The ideal length of treatment was one which would conserve the normal cells, but it was not known. The duration was more important than the quantity when the growth was radio-resistant—for example, gland epithelioma or adenocarcinoma. The dose must not be given in less than thirty days, and the period might be extended up to seventy days in breast cancer. The results were generally good if the total dose was divided into small daily applications of 200 to 300 r each. Cancer could be cured by x rays, but the treatment was very difficult and still dangerous. The patients should be examined daily in order that the dose might be modified if normal tissues were showing signs of damage.

Ireland

Royal College of Surgeons: Charter Day Dinner

At the one hundred and fiftieth Charter Day dinner at the Royal College of Surgeons in Ireland, Mr. Frank Crawley, the president, reminded his audience that at last year's dinner he had expressed the opinion that in the larger towns—for example, in Cork, Galway, and Dublin—there should be an amalgamation or federation of hospitals; for it was generally admitted that the economic unit for a hospital was one of 500 beds. In Dublin most of the hospitals had from 120 to 160 beds; if the three hospitals of 160 beds were amalgamated or made into a federation they would approach the economic unit of 500 beds. When contemplating any new hospital building, Mr. Crawley continued, they must recognize the necessity for more private beds. There could be no doubt but that the general public was awake to the fact that it was a wise thing to go where all the complicated machines necessary to modern medicine were likely to be found, together with the men who could work them. It was impossible, even if the sweepstakes continued to flourish, to contemplate the equipment of each small hospital as it should be equipped and staffed. They could therefore amalgamate or federate, and in his opinion amalgamation was the better way. The tendency of modern medicine was towards team work. Runour, ever a lying jade, had it that throughout the twenty-six counties many small hospitals were to be built, each presumably with one or two

medical men attached. If this proved to be the case then the progress of medical science in Ireland would be put back fifty years. And worse, the treatment of the patients would be ineffective in many cases. He knew many excellent physicians and surgeons in the smaller towns in Ireland, and these towns could be thankful that they had such able members of the medical profession to look after the sick. But no one, having regard to the trend of modern medicine, the expensive mechanical equipment of an up-to-date hospital, and the large number of trained medical men and assistants that were necessary properly to carry out the team work, could hope to equip and staff a hospital in a small country town so as to fulfil the standard of a modern hospital. He hoped that there would always be the general medical practitioner, by whom nine-tenths of the medical cases could be efficiently dealt with, but if the general practitioner had to call in outside assistance he would need to have it as full and as free as possible. If there were to be small hospitals scattered over the country, they should be of the cottage hospital type. Continuing, Mr. Crawley said that the slums filled the hospitals. He knew that the corporation, under the enthusiastic guidance of the Lord Mayor, was making strenuous efforts to get rid of the slums. But it occurred to him that it was very little use to build new, clean houses, and put into them tenants who for generations had contracted insanitary habits. In truth, they had never had a chance of contracting any other habits. The Dutch were building what were called half-way houses, which were allocated to the inhabitants of the worst slums. After a time, when those inhabitants had shown that they could appreciate a more luxurious home, and when their behaviour warranted it, they were moved to a better-class house.

History of St. Vincent's Hospital

On January 23rd, 1834, Mary Aikenhead, of the Order of the Sisters of Charity, opened a hospital at St. Stephen's Green, Dublin, the first in these islands to be organized and staffed by women. Dr. Joseph M. O'Ferrall, single-handed, undertook the care of the patients and the teaching of the sisters, and was the first in a long chain of medical and nursing comradeship within its walls. To commemorate its founding a hundred years ago a handsome volume entitled *A Century of Service* has been compiled, the publishers being Browne and Nolan, Ltd. The story of the institution is told by a variety of authors, and with a personal touch which is often lacking from such histories. In this way the outstanding events are described rather as seen through the eyes of those immediately concerned, and the freshness of the narrative is heightened by excellent illustrations of the past and present buildings. D'Alton Williams, then medical student and poet, gave his services freely in the early days. At first an out-patient institution solely, in 1835 a ward was opened with twelve beds for female patients, the medical staff consisting of Dr. O'Ferrall, then surgeon to Dublin's Maison de Santé, who had already attracted attention by reason of his publication on "phlegmonous tumours in the right iliac region"—a precursor of appendicitis. He was a most active member of the Pathological Society, founded in 1837, and a forerunner of the Royal Academy of Medicine in Ireland. Until his death in 1859, O'Ferrall laboured for St. Vincent's Hospital, which by 1860 had grown to eighty beds, new wards having been opened for men and children. Something of his influence is discernible in the fact that the earliest reference to the equipment of a laboratory is to be found in the minutes of the medical board in 1872, where there is a note about the proposed extension of one already established. The first appearance of a whole-time pathologist was in 1906, and succeeding years saw rapid advances in technique and

equipment, until now it is again being found necessary to make provision for better laboratory accommodation. St. Vincent's Hospital to-day contains seven ward units with nineteen to thirty beds each, and never a bed unoccupied. Of the patients, 65 per cent. are treated without charge, and not more than 10 per cent. of the remainder pay the whole cost. Private wards (St. Anthony's) cater for paying patients, and there are also private homes, all of these being now worked as distinct economic units. In a sense the foundation of the nursing school preceded that of the hospital, for Mother Aikenhead had arranged for the first nurses to be trained in Paris before its opening. That there was something exceptional in the nursing atmosphere is shown by an application from Florence Nightingale for leave to spend three months in its wards. In 1894 the modern system of training secular nurses was introduced, and the nursing school of the present day was inaugurated. Medical students were catered for from the earliest days, and the report contains some amusing reminiscences. *A Century of Service* tells in a series of biographies and personal recollections how a renowned Dublin hospital came into being to meet a great need in a community oppressed by poverty and misery, and evolved with changing times to adapt itself to new opportunities for its work of mercy.

Central Midwives Board

The period of office of the Central Midwives Board for the Irish Free State having expired, the Board has been constituted to function as from February 1st under an Order issued by the Minister for Local Government and Public Health. The following members have been appointed: Dr. J. J. O'Kelly, Mr. M. Stafford, and Senator Kathleen Clarke (appointed by the Minister for Local Government and Public Health); Sir Edward Coey Bigger, M.D., Dr. J. J. Kearney, Dr. Thomas Hennessy, and Sir William J. Smyly, M.D. (elected by registered medical practitioners resident in the Free State); Miss A. Smithson, Miss N. Healey, Mrs. Martin, and Mrs. Margaret Price (appointed by the Minister for Local Government and Public Health after consultation with nursing Associations).

Local Services (Temporary Economies) Bill

Resolutions have been passed by medical practitioners in the county administrative areas protesting against the provisions in the Local Services (Temporary Economies) No. 2 Bill, 1933, for "cuts" in the salaries of medical officers and other officials in the service of local authorities. Many local authorities have also protested against the Bill on the grounds that in some instances the salaries are already on the small side, in others they are quite inadequate, and that, in the circumstances, a reduction would create such dissatisfaction in the services as to interfere with efficiency.

Medical Certificates for School Children

At the last meeting of Cushendall School Attendance Subcommittee the school attendance officer stated that the bad attendance during January was due to an epidemic of influenza colds in the district. While he was satisfied that this was the cause, many of the parents were unable to produce medical certificates in support. The clerk to the subcommittee stated that parents refused to obtain a certificate because it cost them 3s. 6d. Discussing this question of medical certificates for school children, a member of the committee said that no one could blame doctors for refusing to give such certificates free. Doctors had a right to their fees. He thought, however, that some arrangements could be made with the medical profession for the provision of free medical certification in deserving cases, and he

proposed that the committee should call upon the Ministry to take steps in the matter. The figures showing the number of children absent through illness during January were startling, and yet they had not a single proof that the children were actually ill. The percentage attendance returns for the various schools in the district during 1933 were as follows: Culroney, 81.2; Parkmore, 87.5; Kilmore, 83.6; Layde, 85.5; Glendun, 86.9; Ballyeamon, 85; Glenaan, 75.6; Cushendall, 84.1; Knocknacarry—girls 76.9, boys 81.2.

Scotland

Glasgow Royal Infirmary

At the annual meeting of contributors to the Glasgow Royal Infirmary Sir James Macfarlane, who presided, said that demands upon the services of the hospital were still increasing, especially in the out-patient department, where the average number of attendances now amounted to 7,642 per week. The managers proposed to rebuild the out-patient department and the ophthalmic institution upon a new site, as additional accommodation was urgently required for both. It was stated that there had been a deficit of £6,343 on the past year's work, the ordinary expenditure having been £110,100, an increase of £1,500 over the figure for 1932. The expenses, excluding those of the out-patient department, had worked out at 7s. 6d. per patient per day. Principal Sir Robert Rait said that the difficult times of the past few years had inevitably led to a decrease in contributions; he believed, however, that they were entering upon better times, and that citizens would recognize their increased responsibilities in respect of those advances in medical and other sciences which cost the Royal Infirmary a large amount of money. Sir Ernest Morris, formerly house governor to the London Hospital, said that the duties of a medical staff were threefold: first, to bring about the recovery of the patients in the hospital or out-patient department; secondly, to make a study of disease; and thirdly, to teach so that knowledge might be passed on to the doctors and nurses of the future. There were 350 nurses in this Infirmary, which was recognized as one of the best training schools in the country.

Elsie Inglis Memorial Hospital

At the annual meeting of the Edinburgh Hospital and Dispensary for Women and Children, and the Elsie Inglis Memorial Maternity Hospital, Lady Ruth Balfour, M.B., who presided, said that a new ante-natal department was about to be started. The report showed that the expenditure on the hospital for the past year had been £7,254, but there had been a deficit of £2,004 at the end of the year. The total number of cases treated in the maternity hospital had been 1,376 as compared with 1,335 in the previous year, and among these had been 372 abnormal cases. The chairman referred to some valuable research work which had been done at the hospital during the past three years. It was known that the largest single cause of death in childbirth was sepsis, due chiefly to a haemolytic streptococcus, and in the Elsie Inglis Hospital investigation had been carried out to elaborate a system of isolation which should prevent this. The work had been increasingly successful until, in the year under review, there had not been a single case of fever due to this organism. The method consisted in examining every patient during ante-natal treatment, and every member of the staff once a month for this organism. Patients who were found to be free were isolated. Last year 17,000 bacteriological examinations were carried

out. Professor Sydney Smith said the practical application of this research work, which had almost eliminated maternal pyrexia, had been startling. In Scotland generally maternal mortality had risen last year to about 8 per 1,000, while in the Elsie Inglis Hospital it was 2.18. Miss Gertrude Herzfeld gave details of the work at Bruntsfield Hospital, where there had been an increase in both medical and surgical cases. A post-graduate course would now enable six or eight women doctors together to have a fortnight's whole-time course between the two hospitals. There were posts for twelve resident women graduates in the hospitals each year.

Doctors' Prescriptions

An address on "Pharmaceutical Sidelights from the National Health Insurance Central Checking Bureau" was delivered by Mr. A. B. Gilmour, on February 16th, at a meeting held in Edinburgh of the North British Branch of the Pharmaceutical Society of Great Britain. Mr. Gilmour said that the National Health Insurance Act had given to the insured person, among other things, free choice of chemist, and this had removed the objectionable arrangement of code prescriptions, by which doctors sometimes reserved the dispensing of their prescriptions to a particular chemist. A further advantage was that in the case of national health insurance prescriptions there were no bad debts, but a regular monthly payment to the chemists, under the supervision of the Central Checking Bureau. With a staff of fifty persons this bureau in Glasgow last year dealt with 3,700,000 prescription forms. Mr. Gilmour gave some amusing examples of difficulties that had arisen. In one case an assistant medical practitioner, after inserting the name of his principal in the place reserved for the signature, had added his own name, and his illegible signature had caused the dispensing of a porous belladonna plaster. In another, a doctor practising in a working-class district issued a prescription for a four-pound jar of malt and cod-liver oil whenever he called at a house where there were children. The object of this was disclosed when a woman asked the chemist if she might have the malt without the cod-liver oil, as it was nicer on the children's bread-and-butter. As the children were not insured persons this could hardly be regarded as proper and sufficient medicine for the person for whom it was prescribed. Supervision, Mr. Gilmour continued, was also employed to control the prescribing of medicines in extravagant quantities, as in one case where there had been a prescription for one gallon of liquid paraffin, a supply sufficient for half a year in tablespoonful doses. As evidence, however, that the cost of medicines was never allowed to restrict the supply necessary for treatment of an insured sick person, he gave two examples. In one case during a period of eight and a half years $7\frac{1}{2}$ cwt. of boric acid ointment had been supplied at a cost of £113, and in another an insured diabetic in three and a half years had received insulin and other medicines at a total cost of £236.

Central Midwives Board

The examinations of the Central Midwives Board for Scotland, held simultaneously in Edinburgh, Glasgow, Dundee, and Aberdeen, have just concluded, with the following results. Out of 127 candidates who appeared for the examination 115 passed. Of the successful candidates twenty-three were trained at the Royal Maternity Hospital, eleven at the Elsie Inglis Memorial Hospital, and one at the Deaconess Hospital, Edinburgh; twenty-nine at the Royal Maternity Hospital, Glasgow; nine at Stobhill General Hospital; one at the Eastern District Hospital; seven at Govan Maternity Hospital; eleven at

Bellshill Maternity Hospital; three at Motherwell Maternity Hospital; three at Barshaw Hospital, Paisley; four at the Maternity Department, Royal Infirmary, Dundee; five at the Maternity Hospital, Aberdeen; three at the Royal Infirmary, Perth; three at the Royal Infirmary, Stirling, and the remainder at various recognized institutions.

England and Wales

Joint Tuberculosis Council

The winter meeting of the Joint Tuberculosis Council was held in London on Saturday, February 17th, and the members, together with a number of workers in allied fields, were afterwards entertained to luncheon by the chairman, Dr. G. Lissant Cox, at the Hotel Russell. Proposing the health of his guests, the chairman expressed regret at the absence of Miss Olga Nethersole, founder of the People's League of Health, and particularly welcomed Lord Dawson of Penn, who, he said, had not only survived a three-hours' talk with twenty tuberculosis experts in his own house, but had led them in the end to a unanimous decision. Lord Dawson, in an informal acknowledgement of the toast, paid tribute to Miss Nethersole's disinterested pertinacity in a good cause, and mentioned that the Royal College of Physicians had now before it the task of administering the Prophit bequest for research in tuberculosis and in cancer. Sir Henry Gauvain, proposing the toast of the "Joint Tuberculosis Council," said that none of the visitors must imagine for a moment that this was merely a lunch club; it was a most important factor in the anti-tuberculosis campaign. Its members, representing many different aspects and interests, were united in their endeavours; they maintained contact with the general practitioner through the British Medical Association, with medical officers of health through their special society, with pathologists, surgeons, and administrators. They were very fortunate, he said, in their chairman, Dr. Lissant Cox, whose annual reports were masterpieces, and in still having Dr. Ernest Walker as their ideal honorary secretary. Dr. Ward, in his reply, cast a brief glance over the ten years of his secretaryship, and of the council's life, and offered some amusing reflections on the value of resource. Mr. G. S. Elliston, M.P., describing himself as a regular luncher with the society and one who had been associated with Sanatorium Benefit since its inception in 1912, proposed the health of the chairman. This was supported by Dr. Charles Porter, president of the Society of Medical Officers of Health, who said it was a rest for him to go among argumentative people, and by Dr. Jane Walker, who rounded off a sequence of light-hearted speeches with two good stories.

Society of Apothecaries

The Society of Apothecaries of London held a Livery Dinner on February 20th, with the Master, Dr. J. O. Wakelin Barratt, in the chair. In proposing the toast of "The Royal Colleges" Dr. Cecil Wall ably supported his reputation as historian of the Society. This year, he said, represented a triple centenary, for in 1634, 1734, and 1834 the Society of Apothecaries had been brought into contact, not always friendly, with the Royal College of Physicians of London. At the beginning of the seventeenth century the College, a small body of men, had tried to monopolize practice in London and to squash the apothecaries, who not only provided drugs, but gave advice as to their use. Towards the end of the seventeenth century the Apothecaries rented the Physic Garden at Chelsea, but this did not do much until it became the property of the Society through the munificence of Sir Hans Sloane, to whom the Society put up

a statue in the gardens in 1734. In 1834 Parliament inquired into the organization of the medical profession, and at this time the relations between the Apothecaries' Society and the two Royal Colleges was very close. Dr. Wall hoped that the amity between them would continue in the future. In a pleasant speech Sir Charlton Briscoe replied to the toast for the College of Physicians. The real foundation of the old dispute between the Apothecaries and the College of Physicians, he said, was that the Apothecaries of that day were a corrupt lot. Sir Holburt Waring, President of the Royal College of Surgeons, referred to the conference, at present sitting, on the reform of the medical curriculum. Although a report had not yet been drafted, he would make some anticipatory remarks on the matter. He favoured the selection of candidates on physical, mental, and moral grounds. Many men went in for medicine who had no aptitude or were unfitted for it. There should be some kind of vocational selection. We had, he said, gone too far in this country in making examinations everything and the training but little. There could be no skill before practice. Too much was learnt from books and too little from performance. He saw no reason why the curriculum should not be both shortened and lengthened. The elementary sciences might be taught in a more general way, with less detail, and greater attention to exact knowledge should be given in the later parts of the curriculum. In toasting "The Guests," Sir William Willcox, the Senior Warden, said that the Society of Apothecaries was a City company, and City companies excelled in hospitality, which they delighted to offer to their guests. The Society of Apothecaries had as its aim the encouragement of the general practitioner. Sir Francis Fremantle and Mr. G. A. Wathen, Master of the Mercers' Company, replied.

Infectious Disenses among Hop-pickers in Kent

The London County Council five years ago resolved that it was undesirable that London public health authorities should accept responsibility for cases of infectious disease occurring amongst persons who went to districts outside London for hop-picking, the question having been raised by various local authorities in Kent, who were supported by the Kent County Council. The view of the L.C.C. was that cases of infectious disease occurring in a district were the responsibility of the local sanitary authority, and there appeared to be no reason why any particular case of seasonal migration, such as hop-picking, should be exceptionally treated. The late Metropolitan Asylums Board at that time adopted the same attitude as the Council, though it realized that an outbreak of infectious disease among the population of an area largely augmented by temporary migrants might overtax local resources, and offered to assist by receiving suitable cases in its hospitals on the understanding that the authorities responsible would pay the cost incurred. Recently the attention of the Council has been called to two persons suffering from diphtheria who have been transferred from Kent to their home in St. Marylebone, one by ambulance and one by train, apparently with a view to their care becoming a matter for the London authorities. In a report of the borough medical officer of health it was indicated that this course followed some arrangement between the local medical officer of health concerned and the Council's medical officer of health. The St. Marylebone Borough Council has been informed that there is no foundation for the suggestion that the county medical officer was party to any such arrangement. The situation which has arisen, in the view of the Central Public Health Committee, is most serious. The transportation of patients to their homes and thence to hospital would cause delay in treatment which might be injurious to their health, and there

is also a risk to public health if they travel in public conveyances. The committee is proposing to ask the Minister of Health to consider the possibility and desirability of issuing regulations under Section 130 of the Public Health Act, 1875, to provide that the obligations of a local authority for the treatment of persons temporarily resident within their district, who were there found to be suffering from infectious disease, should be the same as for the treatment of persons who were inhabitants of the district. It is stated that after the hospitals of the Metropolitan Asylums Board passed under the Council's management the matter was again raised by the Kent County Council and other local authorities in Kent, and the Board's offer set out above was repeated, but was not accepted.

Moorfields Dinner

The annual dinner of past and present students of the Royal London Ophthalmic (Moorfields) Hospital took place at the Langham Hotel on February 8th. Mr. Elmore W. Brewerton, consulting surgeon to the Royal Westminster Ophthalmic Hospital, was in the chair, and the guests included Sir Holburt Waring, president of the Royal College of Surgeons, Surgeon Vice-Admiral Sir Reginald Bond, Lieut.-General Sir Harold Fawcus, Sir Harold Morris, Sir William Lister and Lady Lister, Professor Edward Mellanby, and Mr. Theodore Luling, chairman of the hospital. There were also present Sir John Parsons, Mr. R. Foster Moore, Mr. R. Affleck Greeves, Mr. Charles Goulden, dean of the medical school, and many other past and present students. In replying to the toast of the school, the dean stated that it was in a flourishing condition and there had been an increase in the number of students during the past year; that at the D.O.M.S. examination, of forty-four candidates from all sources thirty had been successful, of whom twenty-six had worked at Moorfields. At the D.O. examination of Oxford, of the six successful candidates four had worked at Moorfields. During the past year Mr. H. B. Stallard had joined the staff, and among the distinctions which had come to past students he mentioned Dr. Gordon Holmes's election as a Fellow of the Royal Society, Sir Stewart Duke-Elder's knighthood, and the K.C.V.O. bestowed upon Sir William Lister. Both Mr. Whiting and Mr. Goulden had delivered the Montgomery Lecture at the Royal College of Surgeons in Ireland at the invitation of the president and council. Mr. G. Black had been appointed ophthalmic surgeon to the Leeds Royal Infirmary. Mr. Stallard had been awarded the Gifford Edmonds prize, and that among the more senior past students Mr. Mayou had been elected president of the Ophthalmological Society and the dean had been appointed a member of the University of London Board of Advanced Medical Studies.

Testimonial to Dr. Mearns Fraser

The approaching retirement of Dr. A. Mearns Fraser from the post of medical officer of health for Portsmouth is to be the occasion of a testimonial, and an appeal for contributions, sponsored by prominent citizens, has appeared in the local press. Dr. Mearns Fraser has always been a most active member of the British Medical Association. As long ago as 1899 he was secretary for the Section of Public Health at the annual meeting at Portsmouth that year, and in 1923, when the Association again met at Portsmouth, he was president of the same Section. From June, 1925, to May, 1927, he was chairman of the Portsmouth Division, and both during his term of office and since he has shown unremitting zeal in arranging local functions on behalf of the Association's Charities Fund. Subscriptions to the testimonial may be sent to the secretary and treasurer, Mr. Ernest Edmonds, 70, Commercial Road, Portsmouth.

Reports of Societies

RADIO-DIAGNOSIS IN DISEASES OF CHILDREN

At a meeting of the Section of Radiology of the Royal Society of Medicine on February 16th, with Dr. R. S. PATERSON in the chair, a discussion was held on radio-diagnosis in diseases of children.

Dr. B. STURGES, speaking on conditions in the chest, said that, in children, one was concerned more with the lower two-thirds of the lung field than with the apices, which warranted on occasion a slightly different technique. A large number of cases came to Great Ormond Street Hospital from asthma clinics, and he demonstrated a table to illustrate the occurrence of lung damage in association with asthma. About one thousand cases had been investigated, and the statistics indicated that in the hereditary type only slight changes occurred in the lungs, whereas in the acquired type a large percentage showed lung damage, including basal fibrosis and bronchiectasis. In the early stage of tuberculous infection of the lung it was not possible from the radiographs alone to establish a positive diagnosis. With regard to mediastinal shadows, these caused much difficulty in interpretation, and it was quite impossible from the radiograph to decide the origin of a gland lesion in the mediastinum. In the absence of a biopsy, help might be afforded by means of radiotherapy, certain growths in the mediastinum responding rapidly to x-ray treatment, and disclosing their nature in that way.

Dr. C. G. TEALL mentioned certain bone dyscrasias of interest to the radiologist. In rickets, not only did the bones show signs of the development of the condition at an early stage in the disease, but at an equally early stage they gave radiological evidence of commencing healing. The anterior ends of the ribs would supply the earliest radiological evidence, but in practice the lower end of the forearm bones was examined. One of the signs of rickets, cupping at the bone end, was easily simulated by an incorrect position. Cupping was more pronounced in some bones than in others; it was well seen at the lower end of the radius and still better at the ulna, but not at the lower end of the humerus. As the condition progressed, changes occurred in the shaft of the bone. The bones had been described as looking like "ghosts of themselves." Another deficiency disease which concerned the radiologist was scurvy; here again the bone changes were diagnostic. The bones assumed what had been described as a "ground-glass" appearance. The changes were well seen at the lower end of the femur. In congenital syphilis the bone changes were osteochondritis, osteomyelitis—localized areas in the diaphyses—and periostitis, which might arise independently of the other lesions or in association with them. While in typical cases the diagnosis was quite evident, difficulty was sometimes experienced in distinguishing between rickets, scurvy, and congenital syphilis on the radio-diagnosis alone. In general, however, in congenital syphilis the bone changes were not only much more irregular than in rickets but much more irregularly distributed throughout the bones. Passing to certain other disturbances of the growth of bones in children, Dr. Teall mentioned achondroplasia. Here radiographs of the long bones sometimes revealed an apparent thickening of the shafts, but actually the thickening was normal for the age of the child, and it was the shortness which accounted for the abnormal impression. Chondrodysplasia gave rise to a much more varied picture, with irregular growth of the bone ends, curvatures and obliquity of the epiphyses, and unequal length of paired bones. Of osteosclerosis fragilis he had seen only one case in a children's hospital in fourteen years. In the affected parts there was no ordinary bone structure, but a dense sclerosis which was quite opaque to x rays; the areas of sclerosis tended to be towards the ends of the long bones. Another very rare condition of which he had seen only one example was the Schüller-Christian syndrome. Here the chief bone

changes were in the skull, which was affected by a kind of pressure atrophy. The appearance had been described as "map-like" and as "moth-eaten," and both descriptions were true. The bone defects were clear-cut, and the surrounding bone was normal. There were records now of about sixty cases.

Dr. N. B. CAPON said that the children's physician owed a great debt of gratitude to the radiologist, because of the difficulties of paediatrics, the lack of symptomatology in many cases, and the occasional failure of the clinical examination to be a very thorough one. The physicians in Liverpool had the special advantage of working with the disciples of Thurstan Holland, whose skill and honesty had set an example which they followed very successfully. He agreed with Dr. Shires that the diagnosis of tuberculosis in its early stage was not possible in many cases by x-ray examination; it was of the greatest importance to take into account the history of the child's illness and the general appearance; to make a thorough examination, together with observations of the tuberculin reaction, particularly the intradermal reaction; and to search for organisms in the sputum or, if this was not obtainable, in the stomach washings. As to what the radiologist called evidence of an unresolved pneumonia—a small area of shadow—which often came as a great surprise to the clinician, he doubted very much whether these were pneumococcal areas. Very often in the history there was no clinical evidence of any attack of pneumonia, and when one followed the case up it happened that in about ten to fourteen days the shadow disappeared entirely. He believed that the shadow was due, not to the outpouring of exudate into the alveoli, but rather to small areas of collapse, and possibly in some cases to vascular changes such as congestion. Dr. WILFRED PEARSON appealed for closer co-operation, particularly in chest work, between the clinician and the radiologist. He found it still very difficult himself to learn about radiology in relation to clinical medicine, and that was specially obvious when he was trying to teach the student. In these days, when the tendency was to go to special methods first before examining cases, such co-ordination of clinical and radiological evidence became more important.

Dr. J. F. BRAILSFORD spoke of the radiological appearances in the Schüller-Christian syndrome, which, he thought, should be called Schüller's disease. Professor Artur Schüller having first described the condition and the characteristic skull lesion in 1915. The chondrodystrophies, he thought, should be separated out, and as they were definite entities this could well be done. Achondroplasia had a distinct radiographic appearance. The shortening of different bones showed perplexing variations. He had recently seen a case of achondroplasia in which the shortening was confined to the extremities; but whereas in ordinary achondroplasia the fibula was longer than the tibia, in two cases in a family of eight the fibula was only half the size of the tibia. In chondrosteodystrophy the dystrophy occurred in the growing bone, and consequently fragmentation and irregularity were seen, either in the epiphyses or in the end of the diaphyses. In some cases the epiphysis only was involved, the diaphysis exhibiting no changes; in others the reverse was the case. In multiple chondromata the clinical condition might point to a unilateral dystrophy, while radiologically there were lesions on both sides. A proportion of patients with multiple chondromata at the age of about 30 developed sarcomatous changes. In multiple exostoses a definite bony protuberance was observed from the extremities of the diaphyses, not from the epiphyses. In hyperthyroidism the changes were such as might simulate those of osteochondritis. Dr. G. VILVANDRE considered that there was no justification for making a definite diagnosis of such a disease as hyperthyroidism on x-ray evidence of the bones only. Far more important was the investigation of the blood calcium. Some cases were typical, but many were marginal.

Dr. S. VERE PEARSON suggested that where tuberculosis was suspected in a child it might be well to take two or three films at the same time. It was desirable to have

the more highly penetrating rays in order to bring out the signs of hilar disease, and also desirable to take separate radiographs for the investigation of small and early lesions in the lungs. Very often the oblique—especially the right anterior oblique—positions would be helpful. Dr. TEALL suggested that another discussion should be held on diseases to which at present it had not been possible to put a name. The only thing to do with the bone dyscrasias was to make a broad classification; otherwise there might be a multiplicity of descriptions to each of which was attached the name of some individual.

RADIUM TREATMENT OF CANCER

At a meeting of the Liverpool Medical Institution on February 8th, with the president, Dr. J. MURRAY BIGH, in the chair, Mr. G. C. E. SIMPSON opened a discussion on radium in the treatment of cancer.

In an account of the cases of cancer of the breast treated under the auspices of the Liverpool Radium Committee in the last four years, he described the methods of interstitial and superficial radium treatment. The dosage, he said, had to be adjusted to each individual case, and there was need for careful observation. Radium treatment should entirely displace partial operation in the advanced cases, and should be used as an adjuvant to operation in the early or medium case. He hoped that in time a technique would be evolved that would replace radical operation by interstitial or other radium treatment.

Mr. F. STRONG HEANEY gave an interim report on ninety consecutive cases of cancer of the mouth treated by him with radium at the Liverpool Radium Institute since 1930. The cases were grouped according to the stage of the disease and the part affected (Stage I, limited primary, no glands; Stage II, limited primary, mobile glands; Stage III, extensive primary, and/or fixed glands). Regionally the cases were grouped as lip, tongue, and mouth fauces. The number of lip cases, Mr. Heaney said, was small, as excision of the primary was still considered the method of choice. Radium was employed when the disease involved a large part of the lip and when operation would mean a wide excision and complicated reconstruction. In all cases which could be traced the primary had healed. As regards tongue and mouth cases there was healing of the primary by radium in 100 per cent. of all cases treated in Stages I and II, and 65 per cent. in Stage III. Treatment of the glands in all cases in Stage II, and in some of Stage I, was by block dissection. In some instances this was followed by irradiation by radium pack. The glands in Stage III were treated with radium—sometimes interstitial, usually superficial—pushed to the production of vesication. The survival rate in tongue and mouth cases for all stages of the disease was: first year 50 per cent., second year 34 per cent., third year 25 per cent. In fauces cases the treatment of the primary at present consisted of the application of needles interstitially. The needles were threaded with dental wire, the end of which passed through the eye, being twisted round the main stem and cut short to form a barb. This was a modification of the barbed needle introduced by Mr. McGibbon. Better access was obtained in many cases by slitting the cheek and at once joining skin and mucosa. The number of fauces cases was not enough to work out survival percentages.

Mr. P. MALPAS gave the results obtained in a continuous series of 373 cases of carcinoma of the cervix referred for treatment from July, 1929, onwards. In eight of these the disease was found to be too advanced even for palliative treatment. In the remaining 365 radium therapy was employed as the primary method of treatment, although the series contained eleven cases in which a hysterectomy, either local or extended, had been performed elsewhere. All untraced patients were reckoned as dead. According to the League of Nations classification, thirty cases (8 per cent.) belonged to Stage I, the operable group; 105 (26 per cent.) to Stage II, the doubtfully operable group; 142 (39 per cent.) to Stage III, the advanced group; and ninety-six (26 per cent.) to Stage IV,

the hopeless group. The high percentage of cases in the later stages of the disease was due not to delay by doctors in referring their cases, but rather to neglect by patients of trivial haemorrhages, or to the fact that the lesion was in some cases quite symptomless until well advanced. The Stockholm technique was adopted throughout the series without any substantial variations. Most of the cases received continuation deep x-ray therapy after completion of the radium treatment. Both Dr. Whitaker, who gave this treatment, and the speaker considered this a necessary adjunct to radium therapy. There were sixteen deaths immediately or within one month of completion of treatment. Fourteen of the deaths occurred in the Stage IV group; the other two were in Stage III. The total operative mortality was thus 4 per cent., but the mortality in the earlier cases was nil. Including all cases referred, and observing Winter's criteria, the interim results were as follows: survival for one year or more after treatment, 56 per cent.; two years or more, 39 per cent.; three years or more, 36 per cent.; four years or more, 30 per cent. The corresponding survival rates for the cases classified according to the stage of the disease were as follows.

	Stage I	Stage II	Stage III	Stage IV
Survival of 1 year or more	Per cent. 83	Per cent. 83	Per cent. 56	Per cent. 22
" 2 years "	78	61	36	7
" 3 " "	73	61	31	0
" 4 " "	100 (2 cases)	50	20	0

While there were a few disappointments in the early cases, the results seemed satisfactory, certainly in cases falling into Stages I and II. In the majority of all cases a complete healing of the primary lesion was obtained, but treatment failed to prolong life in any of the advanced cases in Stage IV for more than two years.

Mr. M. J. BENNETT JONES said that he had tried to compare the results of the different methods of treatment of all cases of carcinoma of the breast treated by Mr. Woolfenden. Interstitial radium alone was employed in a small series of advanced and otherwise inoperable cases. One-third of these patients had lived for nearly two years without evidence of recurrence; the remainder had nearly all died of widespread metastases, but they usually obtained relief until a very short time before death. Radical mastectomy, followed by radium insertion, was used in a consecutive series of eighteen operable cases (61 per cent. had microscopical evidence of metastasis). Seven of these patients had lived for nearly two years without signs of recurrence. The remaining eleven were all dead, and yet there was only one local recurrence—a case of adenocarcinoma.

Dr. E. CROXIN LOWE said that there appeared to be growing evidence that the result of cytotoxicity of cancer tissue *in situ* was associated with some form of immunizing response in the patient. This had been noted as one of the results of experimental research by several observers in the last few years, and some had also recorded evidence of serological changes accompanying the local destruction of malignant growths in animals.

Mr. JOHN T. MORRISON said that his experience of cancer of the breast treated by radium was a very limited one, as he did not consider it justifiable, in the present state of our knowledge, to neglect the possibilities of cure held out by operation. Consequently, only strictly inoperable cases had been dealt with, and he did not believe that for these there was hope of survival. He was convinced, however, that much good was done by dealing with the local lesion by radium. In only one case had he seen any local recurrence. Mr. Morrison deprecated the idea that radium treatment was devoid of risk. In old people, in particular, local operation under local anaesthesia was to be preferred whenever possible. In old age there seemed to be a great risk of death from a low form of toxæmia coupled with hypostatic congestion during and after radium treatment.

SURGICAL TUBERCULOSIS

At a meeting of the Brighton and Sussex Medical-Chirurgical Society, on February 1st, Sir HENRY GAUVAIN gave an address on surgical tuberculosis in hospital and general practice.

Sir Henry said that tuberculosis might be defined, in all except a few cases, as a general disease in which the local lesion or lesions were a special manifestation. If that definition was accepted, treatment must obviously be directed both to the general condition of the patient and to the local lesions. By conservative treatment he meant the adoption of all measures tending to improve the patient's health, increase his resistance to tuberculous disease, and restore the part or parts specially attacked. This included the prevention or correction of deformities that might arise as a result of the disease. General treatment involved suitable diet, open air, rest, hygiene, discipline, and education. With regard to the last he laid emphasis on the following of an occupation for patients suffering from chronic disease. Suitable occupation or education could easily be arranged for children in special hospitals, but it was equally necessary for children treated in their own homes; the speaker emphasized the importance of handicrafts. Local treatment implied the care of individual lesions, with the avoidance, where possible, of their excision. It must be recognized, however, that operative treatment should have a place even in conservative therapy. An example of this was tuberculous disease of the knee-joint in an adult; in the majority of cases excision of the joint offered the best prospects of a speedy cure. Aids to treatment had rapidly increased in use and popularity in recent years, and among these were sun and artificial light treatment, other forms of radiant energy such as x rays and radium, vaccine treatment, chemotherapy, and balneotherapy.

Sir Henry Gauvain, with a series of slides, then illustrated the methods of treating the majority of forms of non-pulmonary tuberculosis. The way in which treatment by sun and artificial light, and by sea-bathing, was carried out at Hayling Island was demonstrated by special slides. These measures led to a raising of metabolic activity, and this had a beneficial effect on the healing of diseased tissues.

GOLD SALTS FOR ARTHRITIS

At a meeting of the Medical Section of the Royal Academy of Medicine in Ireland, held on February 2nd, with the president, Dr. W. G. HARVEY, in the chair, Dr. JACQUES FORESTIER of Aix-les-Bains gave a lecture on the use of gold salts in the treatment of rheumatoid arthritis and the different forms of inflammatory arthritis, in which he reviewed the basis, technique, and results of the method. He began by discussing the reasons for this treatment, rheumatoid arthritis being, in his opinion, an infectious disease, and then described the laboratory tests. These comprised the determination of the sedimentation rate of the red corpuscles and the resorcin flocculation test, which gave an indication of the activity of the disease and served as a control upon the effects of any treatment, regular examination of the blood being a necessary adjunct to the treatment of chronic cases. The gold salts employed by him were anrothiopropionol sulphate of sodium, thiosulphate of gold and sodium, thiomalate of gold and sodium, aurothioglucose, and aurothioglycolate of calcium. The dose of each drug, he said, depended on the type of case to be treated. He himself recommended series of small doses repeated at regular intervals. Discussing the principles of gold salt therapy in rheumatoid arthritis and the normal reactions, he said that with proper dosage and a good selection of cases severe reactions were rarely met with. Dr. Forestier then summed up the results in approximately 500 cases, followed up during periods of from two to five years. Early cases of under two years' duration were cured in the proportion of 50 per cent., the remainder being greatly improved; cases of older standing were improved in 80 per cent. and cured in 20 to 30 per cent. Lantern slides showing diagrammatically the improvements in the

changes in the joints, etc., were projected, and the lecturer, in conclusion, described the association of treatment by gold salts with different forms of physical therapy and spa treatment.

BASOPHIL PITUITARY ADENOMA

At the annual meeting of the Devon and Exeter Medico-Chirurgical Society, on January 25th, with Mr. R. WAYLAND SMITH in the chair, Dr. C. J. FULLER read the notes of what appeared to him to be a case of basophil adenoma of the pituitary body. The patient, a young man aged 21, was also shown to the meeting.

Dr. Fuller said that it had been noticed that the patient had become progressively red in the face during the past two years, and that this was associated with an increase in weight amounting to 21 lb. in the past twelve months. Recently there had been a complaint of headache, and of a pain shooting down the lumbar region of the back. The fields of vision and refraction appeared to be normal, but the eye muscles were easily fatigued. There was polyuria up to 116 oz. in twenty-four hours, and an occasional granular cast was noted, but no albumin. A blood count in 1932 had revealed a relatively high haemoglobin and a slight leucocytosis, but in a recent count the red cells were increased. The sugar tolerance test showed a high curve, but no glucose or ketones had been found in the urine. The basal metabolic rate was minus 16 per cent. The radiograph demonstrated a slight enlargement of the pituitary fossa. No changes were found in the long bones. The symptoms were further associated with a condition of complete virginity.

At the last meeting of the Cork Clinical Society, held in the University College, Dr. WILLIAM EVANS, who had come from London at the invitation of the society, delivered an address on "Angina Pectoris—its Problems and Treatment." The meeting was very well attended, doctors from the city and from all parts of the county being present. The lecturer dealt first with the clinical definition of the condition, and he reviewed the pathological basis, especially stressing modern ideas on the subject, dividing the cases into the two broad classes—*ischaemic* and *thrombotic*. He then surveyed the symptoms, signs, and other clinical points, and finally dealt with the treatment of the different types. The lecture was illustrated with numerous lantern slides showing comparative tables of symptomatology and of the trial of various drugs in treatment.

The twenty-first annual report of the Collis P. Huntington Memorial Hospital for Cancer Research, which is associated with the Cancer Commission of Harvard University, relates to the year ended June 30th, 1933, and outlines the investigations that are being conducted. Comparison of 1918-22 with 1923-6 shows that there has been an increase in the rate of cures of nearly 20 per cent. in cancer of the lip, and of 100 per cent. in cancers of the mouth. This improvement is continuing, thanks to improved methods of treatment and the rising ratio of early cases, and it is expected that a corresponding examination in five years' time will reveal still better figures. In the series of 1904 only 16 per cent. of cases of cancer of the breast were free from recurrence five years later; in later periods the percentage of cures advanced continuously until with the cases of 1926 there were 40 per cent. remaining well after five years. The main points being investigated at present in the chemical and medical departments are the influence of cell ferments upon the chemical activities of normal and tumour tissues, the influence of the internal secretions upon growth and upon ferments and the physico-chemical study of the cells of tumours as compared with normal cells. Another line of investigation is into the effect of the anterior part of the pituitary gland on the body ferments. No evidence was obtained that aluminium and lead had any effect on the acceleration or inhibition of tumour growth, nor that thyroid extract influenced the effective concentration of the bone enzyme, phosphatase.

CORRESPONDENCE

Pathology of Cancer

SIR,—In the *British Medical Journal* of January 13th there is a short leader on "A Treatment of Cancer," based on the work of Professor Fichera of Milan, who has been experimenting for some years in a treatment by biological therapy. Other biologists have also recently made somewhat similar references. This has appealed strongly to me, as I have spent a great part of my life in pathological work connected with cancer, and have operated on and carefully investigated many thousands of cases of tumours of all sorts. From first to last I have consistently opposed the view that cancer was in any way associated with an infective germ, except in the way of sometimes preparing the ground for growth.

I have often given my reasons for this, but rarely obtained any appreciation of them. The last occasion on which I mentioned these reasons was about fifteen years ago, at a discussion on cancer at the Liverpool Medical Institution, and I still have the notes on which my remarks were based. I stated: (1) That all new growths were closely related to each other and to normal tissue. In fact, taking the whole series from a normal foetus, through monsters, teratomata, complex-tissue tumours, innocent growths, slightly malignant growths (recurrent fibroid, myeloid, etc.), to cancer and sarcoma, no definite line can be drawn. There are connecting links throughout. (2) New growths invariably reproduce the tissue, perfectly or imperfectly, of the structure in which they originate. In all innocent growths the structure is very closely allied to the normal, and in many malignant growths the normal is clearly copied, as in cancer of thyroid, liver, stomach, and bowel, and as in sarcoma of bone or cartilage. If there is no real dividing line between the different forms of new growth or between some of the growths and normal tissue, and if they, innocent or malignant, repeat the structure of the tissue in which they originate, surely this means that all tumours are merely an abnormal form of ordinary tissue growth, at first local and harmless, but later liable to take on malignant features. What we need to know is, How do new growths first come about? Throughout life all tissues can be stimulated into growth, when necessary, and controlled when no longer necessary. The power to stimulate and control growth is always present. Nothing illustrates better the influence of stimulation and control than the effect resulting from the removal of one kidney when the other is healthy. We all know that the one which remains grows to about double size, and then stops. The natural call for more kidney tissue leads to its development, and when fulfilled no more is added. There is no doubt that normal tissues easily respond to the stimulus of a normal call for increase. Surely it can only be due to a somewhat similar though erratic call that causes a tissue to reproduce itself in the abnormal form of a new growth.

Also, on the other side, control or suppression is not confined to normal tissues, but is frequently met with in tumours. Apart from innocent tumours, I think there can be no doubt that malignant growths are sometimes definitely suppressed. I have seen several cases which I could account for in no other way, and accept the view that it is quite possible for a cancerous growth to undergo natural retrogression and disappear.

Suppression may be much more frequent in the early stages than we imagine. In 1900 I became much interested in involution mastitis (*Rep. Path. Soc. London*, 1900), and, recognizing it as a source of cancer, removed a very large number of breasts for this affection. The

specimens constantly showed, among the overgrown gland tissue and cysts, quite a number of small but definite tumours, some fibrous and some glandular. Now the present interest of this is that after a long series of excisions I began to ask myself if operation was always necessary, and decided that it was not. So from about 1910 to 1930, with few exceptions, I only removed these organs when the family history regarding malignancy was unsatisfactory. In this way for twenty years I was in touch with a large number of people who had very definite mastitis, and in whom it subsided, no harm resulting. Many of them must have had the small growths so frequent in such cases, and these must have been suppressed.

Another suggestion of suppression of a temporary nature is seen in cases of cancer of the breast after excision. Every now and then one would have a patient who continued well for from, say, seven to ten years, and then would get a recurrence. Such recurrence would generally be in the lymphatic system, and would always be definite breast cancer of the same type as the original growth. Now lymphatic tissues cannot originate breast cancer, nor would any fresh growth commence in such a scattered manner. These growths must have been there in minute size ever since the operation, but suppressed until the recent growth.

Other ways in which suppression occurs are met with. For instance, I have seen several tumours almost entirely disappear before a fatal termination, so that one could hardly find anything for the microscope at post-mortem examination. Professor Blair-Bell's lead treatment may do the same. Then there are the cases in which secondary growths are found without a primary, which has apparently been suppressed. There is much to suggest that more than one tissue in a tumour patient is prepared to take on new growth. Multiple innocent tumours are common. In malignant cases it is rare to find a multiple origin, but I have seen as many as five rodent growths start together; and in old people it is not very uncommon to find, after removing a small skin epithelioma, that others follow of like nature, sometimes several. Also it is quite common to find, when you have successfully dealt with a cancer, that another growth turns up of a different character in a different part of the body: such as epithelioma of tongue cured, and later a primary growth in the rectum; or a carcinoma cured, and a sarcoma starts later somewhere else.

These things suggest that when new growths take place, especially malignant growths, the tissues have already become generally unstable and are easily stimulated to grow, but the growth is erratic and very resistant to inhibition. This seems to indicate that the body tissues have lost that standard of perfect health which held them equally ready to respond to stimulation or inhibition. They have weakened on a fundamental point, have become unstable, and will grow without proper cause, and fail to respond to proper limitation. This is tumour growth.

In searching for the cause of such a change one must take into consideration a wide field. Cancer is a very old disease, but there is no doubt that it has been steadily increasing, and it is now more frequent than it has ever been before. It is widespread too, and affects some animals as freely as men. In men I believe it is more common, much more common, among the highly civilized races than those leading a natural wild life. In animals, too, it is much more common in the domesticated breeds than in wild beasts. Are there any allied features in the two which might suggest a similar possible cause for unstable tissues, after perhaps an influence extending through many generations? I think there are two. One is that since the days of prehistoric

man the evolution of a gradually increasing civilization has encouraged a steady increase of the condition referred to as "oversexed," and in the high breeding of dogs, horses, cattle, sheep, fowls, etc., a similar condition is induced. The second cause I believe to be high feeding, especially the too free use of stimulating meat foods and possibly an excess of vitamins. This holds good for animals as well as men. The prize dogs and other beasts are fed to the last degree that they may look well and be equal to the service required of them.

Research on these lines is a difficult matter, for it may be that such habits need to go on for countless generations before the normal control of tissue is weakened and ultimately overcome. But with the splendid opportunities now available, and so many good men trained to the work, it may not be impossible to determine how tissues become unstable, and produce growths in the highly fed and oversexed animals. If there is any truth in the views I suggest the lessening of malignant disease must be a long, long process. The instability of tissue which has developed through so many centuries will continue, because the circumstances which induced it will continue. But at any time a researcher may have the happy fortune to discover a control which might operate by inhibiting growth in one specific class of tissue, and, if so, others would follow, one by one, until all growths became controllable. Not, perhaps, as perfect a cure to aim at as regaining normal tissues; but this would involve a return to the simple habits of early man and wild animals. It would be a possible present-day cure, against the impossible return to wild nature.—I am, etc.,

Grayshott, Surrey, Feb. 14th.

FRANK T. PAUL.

Cancer Research

SIR,—For many years, at great expense, cancer research has been carried out by large numbers of devoted workers in the laboratories of this and of other countries. The continued failure of distinguished scientists to obtain any useful results, as far as the disease in man is concerned, shows that they must be working on unfruitful lines suggested by false conceptions of the nature of this human scourge. Clinical observation and experience and a study of the incidence and spread of cancer in man point to the conclusion that it is essentially a deficiency disease, and that the key to its prevention and treatment lies in the diet, the proper correction of which will ensure the reinstatement of man's natural resisting power. The British Empire Cancer Campaign experts appear to believe that the disease is unrelated to diet. "One cannot, therefore, be surprised that the campaigners are making no headway against this enemy of mankind."—I am, etc.,

Cardiff, Feb. 17th.

W. MITCHELL STEVENS.

"The Opportunities of Medicine"

SIR,—Pearls of great price are sometimes to be discovered in your leading articles, and I claim to find one in your appreciation of Sir George Buchanan's "Forty Years in Public Health" (February 10th, p. 247). Sir George, you say, "was one of the small body of men of different nationalities which since 1919 has insisted on the opportunities of medicine in the field of international co-operation." My first thought was that, just because of the paramount importance of internationalism in medicine, broad-minded leaders of our profession must surely, long before 1919, have seen the necessity of its recognition.

Sir William Osler constantly wrote on catholicity in medicine, and inveighed against "the cursed spirit of intolerance, conceived in distrust and bred in ignorance, that makes the mental attitude perennially antagonistic to

everything foreign, that subordinates everywhere the race to the nation, forgetting the higher claims of human brotherhood." In his address on Virchow he speaks of the physician as belonging to "a guild which owes no local allegiance, which has neither king nor country, but whose work is in the world." True, these words were written in 1891, before the world tragedy destroyed a generation and arrested all international co-operation. It is, of course, so obvious as to be a truism that without international co-operation preventive medicine and social hygiene are but empty names, and the essence of the sentence I have quoted from your editorial lies in the words "the opportunities of medicine." They open up a marvellous vista of possibilities.

The power of the profession of medicine, organized and directed to international co-operation, is unlimited, or rather, alas! limited only by one event—namely, war. But that event has proved so destructive of all co-operation that it is surely worth our while to pause and recognize its paralysing and deadly effect. Some of us, perhaps a small minority, have come to see in war the absolute evil, to realize that that is the lesson not only of the whole history of our civilization, but also of the present state of the world around us to-day. What is the attitude of our profession towards the fact that we, whose whole object is the saving of human life, must, in war-time, contribute to its destruction? Can some of our leaders state it? I am well aware that many would disagree with the statement that war is the absolute evil. Sir James Barrie, for instance, eloquently disputes it. In his address some years ago as Lord Rector of St. Andrews University he said: "There is a form of anaemia that is more rotting than even an unjust war. The end will indeed have come to our courage and to us when we are afraid in dire mischance to refer the final appeal to the arbitrament of arms." Can anyone point to a case of this anaemia, and has the appeal to arms ever given any arbitrament at all as to right and wrong?

I make no apology, Sir, for asking these questions in the columns of the *British Medical Journal*. They arise out of your article, and may go to the heart of the world's problems to-day. To refuse to face them, or to say that they do not concern us, is the only rotting anaemia and lack of courage I know.—I am, etc.,

Cannes, Feb. 12th.

A. A. WARDEN, M.D.

Education for General Practice.

SIR,—The suggestion made by Sir Cuthbert Wallace in his Hunterian Oration that "it might be helpful if a hospital could arrange with some of its sons to take qualified students for a limited period as apprentices, thus returning, in a way, to an old custom" (*British Medical Journal*, February 17th, p. 273) will, I am sure, meet with approval from many general practitioners. At a time when the whole scheme of medical education is being submitted to a critical survey, I venture to suggest that this proposal deserves a very thorough consideration by those in whose hands rests the fate of future generations of students.

In view of the fact that by far the greater number of students, whether they like it or not, will have, from force of economic necessity, to adopt general practice as their means of livelihood, it is rather remarkable that the teaching from start to finish is entirely in the hands of specialists. For obvious reasons it must to a great extent always remain so, but I submit that the general practitioner would have information of value to impart were he given the opportunity. The outlook of the hospital consultant must to a certain extent differ from that of the family doctor, whose contacts with his patients are so intimate and personal, who has to take into account

when giving advice so many other considerations than a pure diagnosis and the ideal form of treatment.

I dare to say that in whatever branch of the profession a student may ultimately find his life's work, even if it is to be as a pure laboratory worker, some experience of the ways and shifts necessary in general practice would prove of the greatest value. It should not be a difficult matter for the schools to exercise a wise discrimination when making a selection of those men to whom apprentices might be assigned. Such a plan would do a great deal to raise the professional status of the general practitioner, which has probably never been lower for a hundred years than it has been of late, thanks to legislative oppression, economic depression, public suspicion, and the progressive multiplication of extra diplomas.—I am, etc.,

Bridlington, Feb. 17th.

C. J. GORDON TAYLOR.

** We publish in this week's *Supplement* a paper on "Medical Education as a General Practitioner sees it," by Dr. Arnold Gregory, who concurs in the suggestion made by the British Medical Association's Committee on Medical Education, that during the final year of training a student might be given the opportunity of gaining experience as "pupil assistant to an approved general practitioner."—Ed., *B.M.J.*

Sudden Circulatory Failure and Diabetic Coma

SIR,—In reply to the letter by Dr. Fuller and Dr. Himsworth, in the *Journal* of February 17th (p. 305), I think it would be helpful to refer them to an illuminating article by Dodds and Robertson (*Lancet*, 1930, i, 852), dealing with the cause of death in diabetic coma. These workers showed that there is no constant relation between diabetic coma and the degree of acidosis or of ketosis. On the other hand, circulatory failure, as evidenced by a persistently falling blood pressure, invariably precedes death in coma.

Since reading this publication I have had the opportunity of witnessing four patients in diabetic coma who responded to the usual treatment, in so far as they fully recovered consciousness with control of the diabetes, but who, nevertheless, died suddenly in twelve to twenty-four hours afterwards. In each case the blood pressure during coma was 70 mm. Hg or less, and with apparent recovery this failed to rise more than 10 mm. Hg.

The questions posed by Drs. Fuller and Himsworth can then be answered: (1) Intravenous administration of fluid had nothing to do with death. (2) Collapse was probably accelerated by the sudden raising of the patients from a recumbent position, on account of the profound circulatory weakness. Presumably the blood pressure in their cases was very low.—I am, etc.,

London, W.1, Feb. 19th.

A. H. DOUTHWAITE.

Radiology and Chronic Appendicitis

SIR,—Mr. Muir Dickson, in his article in the *Journal* of February 3rd (p. 184), suggests that the radiological examination for this condition is disappointing in its results. I have examined a considerable number of cases in the East Suffolk and Ipswich Hospital during the last few years. The operative findings in every case have been compared with the radiological report by myself, and these have been found to agree in a most satisfactory manner.

The technique consists in giving the patient 1 oz. of castor oil on the night before the examination; by this means it is possible to see the appendix filled in over 90 per cent. of cases. The stomach is examined early the following morning, and subsequent attendances are usually required at the end of

three, eight, and twenty-four hours. The appendix is generally seen at the eight- and twenty-four-hour examinations. During the first two attendances the stomach and duodenum are examined thoroughly. This is of importance, because duodenal ulceration may accompany or may be difficult to differentiate from chronic appendicitis. The gastric emptying is observed closely, because in a number of cases of this condition an intermittent pyloric spasm has been noticed. Delay in the emptying of the small intestine is also of significance when taken together with other signs.

The most important observations are those made when the appendix is filled with barium and so can be visualized on the fluorescent screen. In the normal it is seen to fill well and to move freely on palpation. When it is the seat of pathological changes it will frequently fill imperfectly. It will not move freely on palpation, and definite tenderness can be localized to it. Kinks can be clearly defined, and by taking skiagrams while palpation is being maintained this can be demonstrated in subsequent radiograms.

A radiologist is not expected to inform a surgeon that a gastric or duodenal ulcer demands operation. He is expected to show, so far as possible, the nature and extent of the ulceration. Similarly, when investigating a case in which chronic appendicitis is being considered clinically, he is able fully to demonstrate whether the appendix is normal, whether it is fixed partly or wholly by adhesions, and whether the patient's tenderness is localized to this organ or to a point removed from the appendix; he is further able to give suggestions as to whether these changes are active or not. I would illustrate this by a child I saw recently, who undoubtedly had adhesions in the region of his appendix, but his tenderness could be definitely localized to a spot a small distance from this point. This confirmed the clinical diagnosis of inflamed mesenteric glands.

Finally, the important differential diagnosis of visceropositis can be determined or excluded with certainty.—I am, etc.,

Ipswich, Feb. 8th.

C. H. C. DALTON.

Artificial Pneumothorax in Children

SIR,—I append a summary of the cases of pulmonary tuberculosis treated by artificial pneumothorax at the East Anglian Sanatorium, Nayland. The first case was induced in 1912, and since the opening of the children's section forty-six cases in all have had this form of treatment. I have divided the cases into those who were T.B.+ and those T.B.—, and naturally the results in the latter are very much better. The extreme seriousness of the nature of the disease in girls in the early teens will be observed, and the high mortality rate.

Cases with T.B.+ Sputum.

Ages 5 to 8 years: 1 girl, died.
1 boy, recovered.

Ages 9 to 11 years: 1 girl, died.
1 boy, recovered.
1 girl, recovered.

Ages 12 to 15 years: 9 girls, died.
3 boys, died.
12 girls, recovered.
1 boy, recovered.

Cases with T.B.— Sputum.

Ages 4 to 8 years: 2 girls, died.
1 girl, recovered.
1 boy, recovered.

Ages 9 to 11 years: 2 girls, recovered.
1 boy, recovered.

Ages 12 to 15 years: 1 girl, died.
5 boys, recovered.
3 girls, much improved (not finally traced).

—I am, etc.,

G. ELEANOR SOLTAU,
Assistant Medical Superintendent,
East Anglian Sanatorium.

Nayland, Colchester, Feb. 12th.

SIR,—As Dr. William Stobie puts to me some definite questions in his letter of February 4th I feel I must trespass further on your space to reply to him, and in doing so I would like to mention that a great many of the cases about which I wrote were under the care of my predecessor, Dr. Cuthbert Agassiz, with whom I have discussed the matter before replying. I agree with Dr. Stobie that many cases of tuberculosis in children are of the benign type, which get better without special treatment, but this is certainly not true of the cases about which we wrote—namely, those with positive sputum, in which the prognosis is generally recognized to be very bad.

In reply to his questions I would like to say:

1. That in the majority of cases the evidence for diagnosis of pulmonary tuberculosis was based on definite physical signs plus evidence of tubercle bacilli in the sputum.

2. Of the 132 cases of artificial pneumothorax mentioned in the previous letter, 124 (94 per cent.) had positive sputum. The few remaining cases showed ample clinical and radiographical evidence of disease, most of them with cavitation, which were not responding to the usual methods of treatment.

3. It does not appear necessary to answer the third question, as in the majority of cases tubercle bacilli were found in the sputum.

Dr. Stobie also says that experience of so many cases must be very rare, and in reply to this criticism I would like to remark that since 1925 we have records of 533 cases in which tubercle bacilli were found in the sputum in children of 15 and under; ninety-one of these were aged 10 and under, the youngest being 1 year old.—I am, etc.,

A. G. L. READE, O.B.E., M.R.C.S.,

Brentwood, Essex,
Feb. 19th.

Medical Superintendent, High Wood
Hospital for Children.

Pruritus Ani

SIR,—In your issue of February 17th (p. 309) Dr. F. Hernaman-Johnson says: "The causes [of pruritus ani] enumerated by Mr. Morley are well known to the family doctor—more particularly the role of parasites." This has not been my experience. Four of my patients who had suffered for years from pruritus ani, which eventually was proved to be due to *Enterobius vermicularis*, were medical men, who, moreover, had been examined by many colleagues, but the cause of the irritation had not been discovered; among the varied treatments prescribed two of them had received courses of x rays.

The following brief case history is instructive. A gentleman who had suffered from pruritus ani for about two years was informed that this was due to some small haemorrhoids, which demonstrably were present. On medical advice he had decided to have them removed. I asked permission to examine him when pruritus was active. A very rapid examination, carried out with the help of an electric torch while the patient was in bed at midnight, resulted in the capture of three adult *E. vermicularis*. Appropriate treatment brought about a complete cure of the pruritus. The haemorrhoids are still present, but give no trouble.

The presence of *E. vermicularis* in adults is so often overlooked because the parasites are difficult to demonstrate. One patient, on my request, passed a motion at a moment when these parasites were active in the rectum. The motion contained no worms, nor did I find any eggs in the material in the course of a prolonged microscopical examination.—I am, etc.,

W. P. MACARTHUR.

Royal Army Medical College, Feb. 16th.

SIR,—May I ask you to grant me space to reply to Dr. Hernaman-Johnson's letter of February 17th? I never doubted that in certain cases of pruritus treatment by means of x rays is able to afford some relief. The more

experience I have of this symptom—and I use the term advisedly—the less frequently do I meet with cases in which a thorough and painstaking examination with the speculum and sigmoidoscope fails to reveal a local—that is, in the large majority of cases, a *rectal*—cause. In my opinion there is no such thing as “idiopathic” pruritus: all that that term implies is that a cause has not been detected, not that a cause is not present. One used to hear a great deal of “idiopathic” erysipelas, but most surgeons now agree that there is a breach of surface in every case of that disease, although it may be impossible to find it.

Nor can I agree with Dr. Hernaman-Johnson that most cases of pruritus are sent by the general practitioner after all possible causes have been eliminated. My experience has been that most cases are sent to the proctologist in order that he may make a diagnosis. In the cases I have had in which the *Enterobius vermicularis* has proved to be the cause I have usually found that the general practitioner is as astonished to hear of it as is the patient—sometimes, indeed, he is even sceptical, unless he is present at the consultation and sees the parasite with his own eyes. In my experience, also, few general practitioners are familiar with inflamed crypts, submucous tracks, and so on. Dr. Hernaman-Johnson's suggestion that cases of pruritus should be treated by x rays, and then, if a failure or relapse occurs, that that fact should be accepted as an indication to make a more intensive search for a cause, or to regard the patient as neurotic, strikes me as thoroughly unscientific. It leaves me unrepentant, and I shall continue to follow the more usual course of making a diagnosis—where possible—first and prescribing treatment afterwards.

It is hardly fair of Dr. Hernaman-Johnson to misquote my letter in order to contradict it. Nobody who read my letter in your issue of February 3rd could have imagined that I classed local anaesthetics and x rays in conjunction as though there were any similarity between them. I referred to local anaesthetics as rendering the skin anaesthetic for a longer or shorter period, and to x rays as rendering it more healthy—which they do, as Dr. Hernaman-Johnson points out, by destroying germs in, and possibly under, the skin. My wording was perhaps a little clumsy, but I do not think that anyone (excepting Dr. Hernaman-Johnson) would have attached to it the inference which he suggests. It betokens that he has a weak case that he drags in the fact that in my earlier days I had considerable experience as an anaesthetist in order to imply that my knowledge of all other subjects must be deficient!

I am glad to know that Dr. Hernaman-Johnson does not object to the treatment of haemorrhoids by injection. It is better, however, not to class this treatment as an “operation,” because that word, especially as regards the treatment of haemorrhoids, has a very sinister meaning to patients who are suffering from that condition.—I am, etc.,

London, W.1, Feb. 17th.

ARTHUR S. MORLEY.

Inheritance of Mental Deficiency

SIR.—It is, as Professor Ruggles Gates says (February 10th, p. 264), a question “of adopting the most reasonable interpretation” of the “familial concentration” of mental abnormality; but this involves an examination of alternative hypotheses. My case against the eugenists is: (a) that they will not consider the possibility of any interpretation but their own, and (b) that their interpretation is unverifiable in regard to indefinite characters such as mental illness and defect, particularly when we take into account the smallness of human families and the length of “generations” and impossibility of experiment.

In regard to (a) Professor Gates stands convicted of bias by his two letters. In the first of these he dismissed Dr. Penrose's suggestion of an environmental factor as “hardly worthy of serious consideration.” In the second he states that the germinal theory of transmission “fits all the known facts,” and rhetorically asks whether we can suppose “that a feeble-minded mother and a father suffering from paralysis and dementia would create a better home environment than two normal parents?” I answer that the Mendelian theory fits the facts only in virtue of its infinite elasticity and prodigal use of *ad hoc* supplementary assumptions. Further, it is virtually certain that the father in the case in point was *not* in a state of paralytic dementia during the formative years of the children's lives. (Incidentally, Professor Gates says in his earlier letter that the inheritance of dementia is “unknown.” This is another tendentious assumption. Dementia paralytica is known to be a syphilitic disease and *not* inherited at all.)

But, treating Professor Gates's question quite seriously, there is no reason to suppose that a feeble-minded mother and a father who is *not yet* suffering from general paralysis should not create as good a home environment in certain vital respects as normal people. There are reasons to believe that for the development of healthy minds in children the environmental factors can be arranged in this order of importance: (1) affective harmony between father and mother (which existed in the case in question); (2) equanimity, self-assurance, and a proper distribution of affection on the part of the mother; (3) maternal character; (4) paternal character. The absolute quality of the parental minds is of less importance than any of these, and probably material circumstances are of still less significance. The child's first requirement is a sense of security in the affection of the mother or substitute; its second requirement (for mental health) is the progressive deflection of its interest from its mother on to the world of reality.

It is, of course, impossible to adduce evidence here in support of this hypothesis, which is advanced merely as an illustration of conceivable factors in psychopathogenesis which have never been considered by the geneticists.

There is only one group of facts which might afford decisive evidence in favour of one or other theory. Schizophrenia and cyclothymia are the most markedly “hereditary” of mental diseases (vide Report on Sterilization, *Journal*, January 27th, p. 163); they are also the most definite symptomatically and the least likely to pass wholly unnoticed. For these reasons they are the most favourable for statistical genetic study. They also occur together in the same families with great, but, so far as I know, unmeasured frequency. This frequent concurrence of the two disease-forms suggests that they are the allelomorphous expressions of certain combinations of Mendelian factors. For example, we might be dealing with common formula 9 AB (normal); 3 Ab (præcox); 3 aB (cyclothymia); 1 ab (unknown result). On this supposition, and taking into account all the members of families in which more than one case occurs, we should expect to find the following ratios:—(a) normal to affected members—between 10 to 6, and 9 to 7; (b) cases of præcox and cyclothymia—equal in numbers; (c) taking into account only families where two of the brothers and sisters are affected, the incidence of the two diseases would be as follows: two cases of dementia præcox together, 20 per cent.; 2 cases cyclothymia, 25 per cent.; one case of each disease together, 50 per cent. of 100 cases of dual incidence.

As I pointed out in your issue of January 27th, any possible ratio of affected to normal offspring can be interpreted on Mendelian lines owing to the observational

error; so that here it is a case of "heads we win, tails you lose" for the geneticists. If, however, the facts are found to agree with some such complex group of ratios as that I have indicated, the error of observation would be largely discounted, and the demonstration conclusive as between the Mendelian theory of psychopathic inheritance and such a theory as I have outlined of psychopathic reactions by children to parents.—I am, etc.,

London, W.C.1, Feb. 10th.

IAN D. SUTHER.

Mind and Body

SIR,—We must, I think, agree with Dr. Richard Eager (*Journal*, February 10th, p. 262) as to "the close relation of mind and body," and with his statement that "any physical illness, no matter how slight, has its mental accompaniment, just as most mental states have their physical counterparts." I should like to know, however, what Dr. Eager and other mental experts mean by "mind." To me, various functions and faculties of the body are classified under the term "mind." We all know what the "body" is, though we know much less about it than we would like. I do not even admit the existence of any actual thing called the "mind." There is no such thing known as a mind apart from a body, any more than such a thing as motion apart from moving bodies. We have, I know, been told that matter is itself motion; but I am not aware that anyone has yet definitely asserted that the body is itself really mind. Using the Greek word "psyche" instead of "mind," or the Latin word "mens," only increases the difficulty, because "psyche" is sometimes translated as "life" or "soul."

Infection with malaria has been used as a psychotherapeutic agent. Does the mind become infected with malaria, or only the poor body, which is already afflicted by the presence of a "diseased mind" as well as certain spirochaetes?—I am, etc.,

Blindley Heath, Feb. 12th.

HUGH WOODS, M.D.

The Nutrition Report

SIR,—Your correspondent Dr. D. Campbell Watt writes: "In view of the political use which has been made of the Association's Nutrition Committee's excellent report, and for other more practical reasons, it is unfortunate that the terms of reference were not more specific." He goes on to criticize the high standard of the minimum scales of diet recommended, and is anxious that his criticisms "should be impressed upon all those who take an interest in the dietetic requirements of the unemployed individual leading an indolent life" (*Journal*, February 17th, p. 304).

Possibly Dr. Watt, who writes from Southern Rhodesia, has not seen the recent reports of many of our medical officers of health, with their tales of widespread malnutrition and debility, nor the many published actual diet scales of English working-class families. A short period of practice in one of our industrial towns, or, better still, a few weeks' attempt to live "an indolent life," making payment for rent (at English rates!), heating and cooking, food and clothing, out of an unemployment allowance, might modify his views. No one would grudge his spending what money remained over on "beer, tobacco, artificial silk stockings, dances, cinemas, and football matches."

Many doctors, so far from sharing Dr. Watt's suspicion that the English working-class is unnecessarily well fed, are becoming seriously alarmed at the poor physique, due to underfeeding and bad housing conditions, of millions of their fellow men and women. Their dissatisfaction is not lessened when they learn that meanwhile large quantities of herring are

thrown back into the sea or used as manure, potatoes dug into the ground, and millions of gallons of milk fed to the pigs or sold at a ridiculously cheap rate to manufacturers to be converted into buttons and other 'commercial articles'; while its price for human consumption is artificially raised.

Though political bias must never be allowed to influence us in our professional services to the community, as citizens we are entitled to fashion our political opinions in the light of our medical experience. The fixing of the rates of both unemployment benefit and public assistance is a political matter. So, to an increasing degree, is the regulation of food prices. In the eyes of a large number of both doctors and laymen the prestige of the British Medical Association has been enhanced by the Nutrition Report, and by the Association's courage in upholding its minimum scales of diet against the Ministry of Health.

I submit that the report could be put to no more "practical" use than that it should be utilized as a political weapon, to secure a higher standard of living for our unemployed, by all whose concern is to improve the people's health.—I am, etc.,

London, E.10, Feb. 19th.

HELEN M. JARDINE.

Colonic Irrigation

SIR,—In your issue of February 10th Dr. Ray inquires what amount of training is expected on the part of those who carry out colonic irrigation. "Are they State-registered nurses, members of the Chartered Society of Massage and Medical Gymnastics, or bath assistants who have acquired a knowledge of the correct procedure by constant practice?" This question is pertinent at the present time, because the Chartered Society has undertaken to issue a diploma in medical hydrology to such of its members as desire to take the necessary training; and the syllabus of the course of instruction will shortly be under consideration. The question of the inclusion of colonic irrigation in this course will have to be considered, and may give rise to differences of opinion. It must, however, be settled by the medical hydrologists themselves—that is, by Dr. Ray and his colleagues at spas and elsewhere.

It is really a question of the convenience of organization and of the patient. If the medical men concerned consider that the massense-hydrologist should be trained in this treatment it will be done.—I am, etc.,

R. C. ELSLIE.

London, W.,
Feb. 19th.

Chairman of the Council of the Chartered
Society of Massage and Medical
Gymnastics

Prevention of Deafness

SIR,—My Medical Committee, in considering Circular 1337 (a), Prevention of Deafness, by the Minister of Health, made the following recommendations, which have received the approval of my Executive Committee.

1. That the committee welcome the suggestion of the Minister that whenever practicable the treatment of ear diseases should be entrusted to a medical practitioner who has had experience of this work, and that the services of such a specialist should be made available to all maternity and child welfare centres.
2. That notification should be made to the proper authority by the parent or guardian or medical attendant of every child who at the age of 2½ years appears to be deaf or hard of hearing or who has not acquired some degree of speech, or, having acquired it, has lost it. Notification should be on the lines already existing in the case of infectious diseases.
3. That the existing school service for the treatment of ear, nose, and throat diseases should be developed to greater efficiency, and that otorrhoea should not be regarded as a minor ailment by the ordinary medical service, but be referred for specialist treatment after it has continued for one month.

4. That the present teaching of hygiene in the schools, particularly with regard to the care of the nose, ear, and throat, should be more strongly emphasized both to the teachers and to the children.

5. That definite propaganda work is necessary in order to call attention to the prevention of deafness by the proper care and treatment of ailments which may eventuate in it, and that in this connexion popular lectures and addresses on this subject should be given as widely as possible to meetings of various kinds interested in social welfare.

6. That it is desirable that periodical addresses on the prevention of deafness should be broadcast by the British Broadcasting Corporation.

7. That in order to ascertain the early onset of deafness the testing of school children by the audiometer should be general, and that such tests should be available to other persons.

—I am, etc.,

A. J. STORY,

2, Bloomsbury Street, W.C.1,
Feb. 13th.

Secretary, National Institute
for the Deaf.

Labour in the African Negro

SIR,—May I answer Dr. W. M. Hewetson's criticisms of the figures of difficult labour in African negroes, in the *Journal* of December 2nd, 1933 (p. 1048)?

1. He wonders "how it happens that three hospitals in the same area show a variation from 5 per cent. to 25.6 per cent." These hospitals may be in the same area continentally speaking, but 500 miles puts them in entirely different areas ethnologically speaking. All of them are among different tribes, which vary in origin, stature, skin colour, customs, etc., including birth customs. For example, the old women of one tribe will not allow the woman in labour to rest between pains if beating, holding nose and mouth shut, cold water, haranguing, etc., will prevent resting. The result is that the woman is often tired out before the second stage of labour is over, and uterine inertia follows. Two of the institutions quoted are located in capitals of their respective Colony and Protectorate. The other is in a native reserve, where the native women are naturally more backward about presenting themselves to foreign male doctors before necessary. The result is that a smaller proportion of hospital cases in the native reserve received ante-natal treatment or care from the beginning of labour.

2. He asks: "Can one blame the whole of this [variation in percentage] on the ambulance alone?" In 1933 the hospital in the reserve had only fifty-nine patients admitted before delivery started (that is, they walked in); of these there were only two forceps cases. During the same period 169 women were brought in by car after labour had started and they had given up hope at home; of these there were fifty high or medium forceps cases, or 29.9 per cent. Where does Dr. Hewetson place the blame?

3. Dr. Hewetson forbears "to repeat much that has already been drummed into us on the point of intervention," and quotes the case of premature application of forceps before the cervix was dilated reported by Dr. Owen-Jones in the *Journal* of July 29th, 1933 (p. 214). Why would there be premature application of forceps in an institution with two European doctors (with post-graduate work in obstetrics) who live within a hundred yards of the delivery room if they could produce "a 7 lb. L.O.A. live foetus with the aid of 1/4 grain of morphine twelve hours later," especially if there were two European nurses and native attendants to administer the hypodermic?

4. Dr. Hewetson, trying to read between the lines, suggests an answer, remarking "that mission hospitals with ambulances, and subscribers in England to be 'touched' who provide them, should be more careful to exclude obviously, but also quite unconsciously, tendentious arguments." One of those "mission hospitals" happens to be a Government institution for training native midwives; another similar institution was mission-founded, and is now partially supported by another Government. The third does confess to be nothing but a mission hospital. But it does not, and never did, have an ambulance. Ambulance service is rendered by the doctors personally in their own box-body safari cars; nobody was "touched" to buy them except their respective wives and children, who were short of cash for a year or more afterwards! If any subscribers would have been "touched"

they would have not been in England, as the said hospital gets (or tries to get) its support from another country.

5. He asks us "to correlate their own figures before entering the field of scientific discussion." That may be impossible; but it is possible to make them at least equal to the presumably scientific objections that have been answered. Let us attempt to reduce the highest figure (25.6 per cent.) by limiting it to the last two years, when there were two doctors at the hospital, with presumably more time to make accurate records; also by ruling out all low forceps cases for fear they yet may be considered premature intervention. Let us consider as low forceps any case in which the caput (not skull) touches the perineum, regardless of whether the foetus is alive or dead, regardless of the condition of its heart, regardless of the uterine response to pituitrin, in spite of the fact that some of those cases are difficult deliveries. Then, of the 353 deliveries in the F.A.M. Hospital in 1932 and 1933, there were six high forceps, twenty-eight mid-forceps, and eight craniotomies, making a total of 11.89 per cent. difficult deliveries, to compare with the 5 per cent. and 12 per cent. of the other two institutions. The only comparative "European" figures I have at hand are for high and medium forceps in an American institution, where the percentage for ward patients was 3.29 and for private patients 9.18 (*Amer. Journ. Obstet. and Gynecol.*, April, 1932), and "6 per cent. forceps incidence" in the Rotunda Hospital (*Proc. Roy. Soc. Med.*, January, 1932).

But what were those thirty-one low forceps cases in which the forceps were possibly prematurely applied? Five foetuses were dead before admission or before labour started; fourteen patients had uterine inertia, and twelve of them received pituitrin without any effect; the hearts of five went bad; three presentations were abnormal; and in five there was insufficient information to classify. I will grant, for the sake of argument, that the last five were cases of premature intervention, and should have had 1/4 grain of morphine to tide them over their third, fourth, or fifth twelve-hour period of labour!

I still maintain that the facts show that such statements as "Childbirth in African negro mothers is a thing to marvel at—that is, for Europeans"—is misleading unless limited to a specific tribe. I trust these replies will be received in the same kind and courteous way in which I am sure the criticisms were made.—I am, etc.,

Kisumu, Kenya, Jan. 21st.

Carbon Dioxide in General Practice

SIR,—During one single hour of general practice last week the value of carbon dioxide-resuscitation was very strongly brought home to me: first, a mother with respiratory failure under chloroform during an instrumental labour; secondly, the child, which required artificial respiration before it breathed; and finally, a road accident as soon as I returned home. The road accident, in which a youth received fractured ribs and severe multiple injuries through collision with a motor vehicle, demonstrated most emphatically the value of carbon dioxide resuscitation for victims of road accidents. When I arrived on the scene he was unconscious, almost pulseless, and his breathing was almost imperceptible. I applied a diluted carbon-dioxide-air mixture from a facepiece for a few moments while I examined him. His breathing and pulse improved, and he was fully conscious when he was loaded into the ambulance, although his injuries included broken ribs, fractured shoulder, and a leg crushed from thigh to ankle.

I feel confident that many of our road fatalities are due to respiratory failure within the first few moments after the accident, and that carbon dioxide, made available by a portable supply, will serve a purpose and meet a need for which nothing seems to be available at present in the majority of accidents.—I am, etc.,

Hemel Hempstead, Feb. 17th.

Nitrous Oxide: History and Development

SIR,—In your issue of January 27th you published an interesting paper by Mr. H. Edmund G. Boyle under the above heading. In it he shows how much good work he has done towards popularizing the method in major surgery in this country. As he has mentioned my efforts towards the same object, I should like to correct one or two mistakes in the paper where he refers to me.

The international conference in which he refers was held in August, 1913—not 1912. Dr. Teter gave his demonstration at Guy's in August, 1913. My first paper on "Gas and Oxygen and Ether in Major Surgery" was read at the West London Medico-Chirurgical Society in 1912, and my second paper on the same subject at the Royal Society of Medicine (Anaesthetics Section) in February, 1913. My efforts were therefore made before Teter's demonstration at Guy's, not after, as recorded in Mr. Boyle's paper. It was very interesting to see Dr. Teter using his apparatus for anaesthesia in major surgery, but the method was not a novelty at Guy's, as I had imported the Teter gas and oxygen apparatus a few years before 1913, and had used it frequently at Guy's for the administration of gas and oxygen and ether in major surgery with rebreathing before Teter's demonstration. I showed this instrument at the Royal Society of Medicine when I read my paper referred to above.—I am, etc.,

Guy's Hospital.

Is there a "Fourth Disease"?

SIR,—The existence of a "fourth disease" in addition to the common exanthemata—measles, scarlet fever, and German measles—has often been suggested, and the occurrence of two abnormal cases seen recently would seem to justify a consideration of the possibility.

Case 1.—A female, aged 12 years, recovering from a mild attack of chicken-pox, suddenly developed a temperature of 103° F. on November 23rd, 1933, but showed no signs or symptoms of any disease. Koplik's spots were absent. On November 24th there was a patch on one tonsil which, on culture, showed Vincent's spirillum. November 25th: temperature, 104°; petechial rash on neck and clusters on the body; leucopenia—4,000 white cells per c.mm.; urine—trace of albumin. November 26th: patchy erythematous rash on body; enlarged cervical and axillary glands; temperature 104°; patient seen in consultation with Dr. C. C. Beatty, who suggested an unusually severe German measles. November 26th: typical measles rash on face and neck, spreading to the body and limbs. Temperature remained at 103° to 104° until December 2nd, after which recovery, though slow, was uneventful. On December 7th the patient's sister developed a fever. Koplik's spots were present, and measles developed in the ordinary way and ran a fairly ordinary course. On December 26th the original patient began to desquamate freely, and showed a severe and complete desquamation of the hands, legs, and feet.

Case 2.—A male, aged 28, shivered on January 24th; when seen the next day he had a severe headache and sore throat; temperature, 102°; pulse, 88; no Koplik's spots were present, and the throat looked like a "scarlet." January 26th: temperature, 104°; pulse, 88; no rash; a few glands in the neck. January 27th: temperature, 104°; no rash. January 28th: a few scattered papules on neck and face; rough morbilliform eruption on buttocks, legs, and arms; leucopenia—3,000 white cells per c.mm.; urine—trace of albumin; ulceration of lips and tongue. The rash did not develop on the body, but did on the neck and face, where it became confluent. Temperature remained at 104° till February 4th, and then dropped by lysis. On February 12th patient began to desquamate, and showed a severe and complete cast-like desquamation of pinnae, hands, and feet.

Both cases might well be accepted as severe measles, but the desquamation, in the first case about four weeks after the eruption appeared, and in the second fifteen days afterwards, is so unusual as to warrant the suggestion that the condition was one of simultaneous scarlet fever

and measles. The absence of Koplik's spots and the glandular enlargement is in favour of German measles, but the development in the patient's sister of a typical measles fourteen days after contact is against this diagnosis. The presence of a leucopenia in both cases is in favour of the measles group. One is tempted to speculate on the significance of a leucopenia in these infections, as also in typhoid, influenza, and undulant fever. Leucocytosis is the usual response to infection or injury; but in the diseases mentioned, is a leucopenia evidence of a lack of response to the infection or to a specific action of the organism or virus on the leucopoietic tissues? If a specific action, is there any other evidence connecting these diseases, in two of which—namely, influenza and measles—the aetiology is still obscure?—I am, etc.,

London, N.7, Feb. 18th.

W. LEE'S TEMPLETON.

Medical Examination at the Police Station

SIR,—Mr. Justice Rigby Swift, at the Liverpool Assizes on February 12th, criticized a doctor for telling the police the opinion he formed as to the sobriety of a man on whose behalf he was called upon to make an examination. The brief report in the *Daily Sketch* of the following day does not permit one to judge the merits of this particular case. Clearly the accused's doctor is not justified in telling the police his conclusions till he comes into court—or at least has his patient's consent. Is the police surgeon under similar obligation? This question affords an opportunity for considering from an ethical point of view the procedure of medical examinations at the police station in cases of charges for drunkenness. First of all, the police surgeon is called in and proceeds to examine the accused without saying "By your leave," or "Would you like your own doctor to be present?" This obviously is incorrect. If he is drunk he cannot give consent, and therefore the examination is strictly not legal; if he is capable of giving consent he is not drunk, and therefore the examination for that purpose is unnecessary.

In my long experience of metropolitan police stations I have found that invariably the police surgeon made his examination in your absence, yet he remained, or returned, for your examination on behalf of the accused. Another questionable procedure I have found usually followed the examination of the private doctor—namely, the inspector asks him to write down in the station book his report of such examination. The suggestion is made in such a way that a doctor inexperienced in such matters would be inclined to believe that it is a legal duty, and that the patient would be adversely affected if he declined, and, indeed, the attitude of the police rather conveys that impression when refusal is made. This certainly is not as it should be, and the senior police surgeon is obviously the proper authority to regulate such matters.—I am, etc.,

London, S.W.1, Feb. 15th.

REDMOND ROCHE.

P.S.—Since writing the above I notice in to-day's *Times* (February 15th) that the same judge (Mr. Justice Swift), in another case in the Liverpool Assizes, protests against the methods of medical examination of motorists suspected of being drunk. The judge asked by what right the police surgeon examined the accused, and went on to say: "The police are entitled to ask a doctor to come and observe a man they have in their cells, but they have no right whatever to put him through tests unless he consents. If they say he is able to give consent, then they have no business to come here and say he is drunk, because drunkenness destroys consent." The learned judge later protested against these "inroads on British freedom." It is clearly most desirable that these problems should be solved.—R. R.

Trachoma

SIR.—In your annotation "Ophthalmology in Egypt" (February 3rd, p. 204), and referring to my paper on the Prowazek-Halberstaedter body, you write as follows. "He comes to the conclusion that trachoma without inclusion 'hodies' may be the pure disease, and trachoma with inclusions a secondarily infected form." (Italics mine.) I am afraid that my writing must have been obscure, and I would certainly substitute "is" for "may be."—I am, etc.,

Giza, Egypt, Feb. 11th.

F. H. STEWART.

Obituary

EDWARD JOHN CAVE, M.D., F.R.C.P.

Consulting Physician, Royal United Hospital, Bath

Dr. Edward John Cave died in Bath on February 16th, after a few days' illness, and the city lost one of the most brilliant of the many able physicians that have served her.

Born in 1859, educated at Chard Grammar School, and a medical student at Bart's, Cave graduated M.B.Lond. —with gold medal—in 1885, and two years later obtained the M.D. degree, qualifying for the gold medal. In 1912 he was elected F.R.C.P. After serving as resident medical officer at the Royal United Hospital, Bath, and subsequently at Leeds and Newcastle, he started in general practice in Crewkerne, Somerset, where he was soon recognized as a practitioner of unusually high skill, and medical men who knew his worth when he was resident in Bath persuaded him to return to that city, where he rapidly made a great and widespread reputation as a consulting physician.

Dr. Cave had been a member of the British Medical Association for forty-nine years. He served for two periods on the Central Council, and was a past president of the Bath and Bristol Branch. At the Annual Meeting of the Association in 1925 he was vice-president of the Section of Medicine. He was one of the founders of the Bath Clinical Society, a member of the Bristol Medico-Chirurgical Society, and a member of the Association of Physicians of Great Britain. Though not a voluminous writer, what he wrote was good; among his papers were: "Recent Applications of Bacteriology to Clinical Medicine," "Pneumococcal Arthritis," and "Spa Treatment of Neurasthenia." His contributions to discussions at medical meetings were not frequent, but highly valued for their convincing logic. He went to Bath at a time when a scientific outlook in spa treatment was peculiarly valuable, and he found and inspired able colleagues who have continued the same high tradition which has placed Bath in the position it now holds in the medical profession. He had a large practice among visitors to the baths, mostly sent to him by medical men, among whom his reputation stood so high. But it was chiefly as colleague and consultant that he was known to and valued by the medical men in that part of England.

Gifted with a remarkable memory, a logical mind, and rapid perception, he had all the qualifications for a physician and consultant; a sound, thorough, and up-to-date knowledge of his calling, the result of much reading with critical induction of new ideas of pathology and treatment and a large experience of hospital and private practice; deliberate and thorough in examination, yet a rapid thinker; a quiet but genial manner with a real sense of humour and a sympathy born of the knowledge of the import of illness to the patient. A man of the world, his opinion, given with a dignity peculiarly his

own, with due regard for his colleagues' views, was rational in its appeal and practical in its suggestion for treatment. With nothing whatever in manner or word of affectation or pretension, he had that peculiar personality which gave confidence and satisfaction both to patient and to doctor. Never in a hurry, quiet and unassuming, shunning anything that might savour of advertisement, he was not so much in the public eye as he might have been, but he held that position in the profession and among his patients that nothing could disturb. At one time he talked of retiring and living in the country, for he enjoyed farming and shooting, but the call of his profession kept him to his work, and although of late years he preferred to do less and to take life more leisurely, he kept himself to the very last fully conversant with the literature and practice of the day. He was a brilliant chess player, president of the Bath Chess Club, and played for the county of Somerset; he was also a good billiards player. A man of liberal views and sound judgement in all manner of things, his colleagues and friends looked on his opinion as that of a judge, and now, alas! he is no more there when we may want him. He was a widower, and leaves a daughter, Mrs. Marshall, to whom our sympathy is extended.

Dr. Cave was buried on February 20th at St. Andrew's Church, Bath. A very large congregation of medical men testified to the appreciation and affection of all who knew him.

E. CANNY RYALL, F.R.C.S.I.

Senior Surgeon, All Saints' Hospital for Genito-Urinary Diseases

We regret to announce the sudden death, on February 11th, of Mr. Canny Ryall, at his home in Harley Street. He was senior surgeon to All Saints' Hospital for Genito-Urinary Diseases in Austral Street, E.C., which he himself had founded on a small scale twenty-three years ago in Vauxhall Bridge Road.

Born on May 6th, 1865, Edward Canny Ryall traced his descent from one of Cromwell's officers who settled in Ireland at the termination of the Irish wars. His father, E. C. Ryall, M.R.C.S., served through the Crimea and the Indian Mutiny as surgeon to the 18th and 86th Regiments. His brother, Sir Charles Ryall, senior surgeon to the Cancer Hospital and the Bolingbroke Hospital, London, died in 1922. After studying medicine in Dublin and at several London hospitals, and also in Continental clinics, Canny Ryall obtained the diploma L.R.C.P.Lond. in 1890, and the M.R.C.S.Eng. in 1893, and was elected a Fellow of the Royal College of Surgeons in Ireland in 1900. At the Westminster Hospital he served for some years as surgical registrar, curator of the museum, and senior demonstrator in anatomy and physiology; he was then appointed surgeon to the Westminster General Dispensary and to the Kensington and Fulham General Hospital. A growing interest in genito-urinary surgery, and the possession of ample means, led him, in 1911, to found the All Saints' Hospital, and thenceforward his professional life largely centred in that institution. He was also consulting genito-urinary surgeon to the Clacton-on-Sea and District Hospital, and to the Musicians and Concert Artists' Benevolent Society.

Canny Ryall's book *Operative Cystoscopy*, published in 1925, incorporated the results of many years of study, with an abundance of illustrations by Mr. Thornton Shiells. Many of the instruments described in that work had been invented or modified by the author, and still bear his name. As in his other writings, the letterpress was marked by a strong individual flavour and a dramatic touch seldom found in English surgical authors. The operative measures he advocated have not found favour

with all urological surgeons, though his industry and enthusiasm were widely recognized. A paper on the treatment of calculi impacted in the pelvic portion of the ureter appeared in these columns in 1920, and as long ago as 1907 he had written on the value of spinal analgesia. He was an enthusiastic golfer, and well known to all the members of the Sandy Lodge Club. A challenge cup presented by him, and bearing his name, is competed for regularly at the meetings of the Medical Golfing Society, of which he had been president.

COLIN MACKENZIE, O.B.E., M.D., F.R.C.S.

Surgeon, Bradford Royal Infirmary

We much regret to announce the sudden death of Mr. Colin Mackenzie on February 10th, while on a cruise in the West Indies. He was born in 1883, and was educated at Eastbourne College and Emmanuel College, Cambridge, where he took his B.A. (Natural Sciences Tripos) in 1904. He then went to the Middlesex Hospital, where he obtained the M.R.C.S. and L.R.C.P. diplomas in 1908, and the F.R.C.S.Eng. in 1912. In 1914 he graduated M.B., and also M.D.Cantab. He was junior Broderip Scholar at Middlesex Hospital in 1908. After graduating he served as house-physician and house-surgeon at the Middlesex Hospital, and in 1913 he was appointed resident surgical officer at the Bradford Royal Infirmary. On the outbreak of war in 1914 he volunteered for service, and went to France in the very early days, where he served with a casualty clearing station as surgical specialist, and took part in the retreat from Mons. In 1916 he was appointed surgical specialist at No. 14 General Hospital, Wimereux, under, the then, Colonel John Goodwin. During the latter part of the war he was appointed officer in charge of the surgical division of the same hospital, and had over two thousand beds under his care. For his services he was awarded the O.B.E. (Military Section), and he held the rank of major on demobilization.

After the war Mackenzie returned to Bradford and commenced practice as a consulting surgeon. He was appointed honorary assistant surgeon to the Bradford Royal Infirmary in 1919, and was promoted to the full staff in 1923. He was also appointed surgeon to St. Luke's Hospital, Bradford, in 1920. Both of these posts he held at the time of his death. He was a member of the British Medical Association, and from 1925 to 1931 served as honorary financial secretary of the Bradford Division, and in 1932 he was chairman of the Division. He was a very keen Freemason, and was a Past-Master of the Middlesex Hospital Lodge, and also of the Pentalfa Lodge, Bradford. In his younger days Colin Mackenzie was a Rugby football enthusiast, and he also took great interest in amateur theatricals. Later in life fishing and flying were his recreations, and recently he obtained his pilot's certificate.

As a surgeon, he was a man of outstanding merit; his diagnoses were remarkably accurate, while his judgement and operative technique were very sound. He was a man of sterling qualities, possessing an attractive manner and a keen sense of humour, both of which inspired confidence in his patients, and also brought him a large circle of friends. He would go out of his way to do a kindness, and, no matter what time of day or night it was, he would always respond cheerfully and promptly to a call for assistance. Those who had the privilege of knowing him and working with him feel that they have lost a loyal friend and colleague, whom it will be difficult to replace. He will long be remembered with affection and esteem in the medical and social life of Bradford.

Truly the following might apply to him:

"One who never turned his back but marched breast forward,
Never doubted clouds would break,
Never dreamed, though right were worsted, wrong would triumph,
Held we fall to rise, are baffled to fight better,
Sleep to wake."

A memorial service was held at St. Barnabas' Church, Heaton, Bradford, on February 15th, and this was attended by a very large number of his professional brethren, fellow Masons, and friends. He leaves a widow and four young sons.

W. N. W.-W.

We regret to record the death, on January 29th, of Dr. EMILIE EDUARD FROSSARD, who had practised in Bishop's Lydeard, near Taunton, since 1889. Of distinguished French descent, he was born at Bagnères de Bigorre in 1865, and was educated in Bordeaux. He received his medical training at King's College, London, obtaining the diplomas M.R.C.S., L.R.C.P. in 1889. At one time he was assistant house-surgeon and dresser to Lord Lister. He built up a large practice in Bishop's Lydeard, in the general social life of which he took great interest from the beginning of his residence there. He was public vaccinator for the district, and formerly medical officer to the board of guardians. During the war he served as medical officer to the local prison camp for German officers. In his younger days he captained the local cricket team. He was chairman of the working men's institute, and organized many concerts and other entertainments. About twenty years ago Dr. Frossard's services were recognized by the presentation to him of a motor car and an illuminated address. Although in failing health for several years, he had continued actively in practice, and his death occurred suddenly a few hours after he had been called out at midnight to an urgent case. He had been a member of the British Medical Association since 1892, and was president of the West Somerset Branch in 1902-3. He is survived by his widow and three sons, one of whom is in the medical profession.

Following well-known foreign medical men have been mentioned: Dr. J. CANTACUZÈNE, professor of bacteriology and director of the Institute of Serums and Vaccines at Bucarest, representative of Rumania at the International Health Office in Paris, and former Minister of Health for Rumania, aged 70; Dr. ALBERT HOGGE, professor of the Liège Faculty of Medicine and member of the French Urological Association, aged 66; Dr. WLADYSLAW FILIPOWICZ, director of the surgical clinic of the Protestant Hospital at Warsaw; Dr. J. GORTANI of Terzo Aquile, near Trieste, probably the oldest practitioner in the world, aged 106; Professor EUGEN JOSEPH, for many years director of the urological department of the Berlin Surgical University Clinic, aged 54; Professor GEORG ABELSDORFF, a Berlin ophthalmologist, aged 64; Geheimrat Professor ERNST VON ROMBERG, director of the First Medical Clinic at Munich, aged 68; Professor GEORG ROSENFELD, an authority on metabolic diseases, aged 73; and Dr. ALFRED FAWAN HESS, professor of clinical paediatrics at the University and Bellevue Hospital Medical College, New York, aged 58.

The Services

MEDICAL DIRECTOR-GENERAL R.N.

The Admiralty announces that the appointment has been approved of Surgeon Rear-Admiral Robert W. B. Hall, C.B., O.B.E., M.R.C.S., L.R.C.P., to be Medical Director-General of the Navy, in succession to Surgeon Vice-Admiral Sir Reginald St. G. S. Bond, K.C.B., F.R.C.P., F.R.C.S., M.B., C.M., D.P.H., to date July 2nd, 1934.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The committee stage of the Unemployment Bill and the second reading of the Rural Water Supplies Bill were the chief business of the House of Commons this week. On the former Bill discussion was renewed about the allowances for the children of the unemployed, and references were made to their nutrition.

Sir Hugh Fremantle headed a deputation to Sir Hilton Young on February 19th from the Conservative Health and Housing Committee. The deputation explained that it did not advocate a reintroduction of the housing subsidy, but urged that slum clearance should be supplemented by a vigorous effort for reconditioning houses and encouraging rural housing.

Mr. Hugh Molson, having a favourable place in the ballot, has given notice that in the House of Commons, on February 28th, he will call attention to mental deficiency and to the report of the Departmental Committee on Sterilization; and move: "That this House considers that the facts set out in the report of the Departmental Committee on Sterilization indicate a state of affairs calling for action, and respectfully requests His Majesty's Government to give immediate consideration to the unanimous recommendation of the committee in favour of legislation permitting voluntary sterilization in certain classes of cases." Dr. O'Donovan has tabled an amendment asking the House to declare that "prior to any action on the departmental report, the present law and the origin of the law on the matter of voluntary sterilization should be the subject of a further departmental inquiry." On the same day, if time permits, Mr. Rhys Davies will call attention to national health insurance, and move a resolution.

Mr. Boothby gave notice that on February 21st he would present a Bill to regulate the practice of osteopathy and to prescribe the qualifications of osteopathic practitioners.

Contraceptives Bill

The committee stage of the Contraceptives Bill is set down in the House of Lords for February 27th. The Earl of Listowel has handed in amendments to exempt from the Bill the sale or offer for sale of contraceptives when the offer is made by a registered medical practitioner, a midwife, or a duly authorized representative of any birth control clinic that is not conducted for profit. He also proposes that periodical publications or medical journals recognized by the profession shall be exempted from the embargo against the dispatch to unmarried persons below the age of 18 of all documents containing information relating to any contraceptive.

Duty on Insulin

On February 12th, on the motion for the adjournment of the House of Commons, Commander OLIVER LOCKER-LAMPSON called attention to what he described as a recent most unsatisfactory answer by the Government on the subject of insulin. He said that the decision of the Tariff Commission to impose a duty of 33½ per cent. on imported insulin was a mistake in morals as well as in medicine. A small and unrepresentative committee came to this decision, and recommended legal action. This committee consisted of chemists, and was presided over by a lawyer. After hearing the evidence only of other chemists, the committee decided that insulin was a fine chemical and, in accordance with the legal regulations, the duty was imposed. The truth was that a committee, on which neither the doctors nor the public nor the inventor were represented, sat and imposed, by a technical trick, this tax on poverty and disease. The imposition of this duty had kept out foreign insulin. Before, it was sold from Denmark, and could be purchased at about 6d. After this duty was imposed, insulin could only be

purchased in this country for 1s. 10d., or occasionally 1s. 6d., although this drug could be made at a cost of 2d. a dose. In ordinary illnesses there were many rival drugs, which could be purchased in competition, each of which might achieve a cure. In the case of diabetes there was only one treatment—that was insulin. To-day there were 100,000 helpless and otherwise hopeless victims whom this tax not only exploited but blackmailed. He begged the Government to reconsider its decision, to take over the making of insulin itself, and to stop commercialization of misery.

Mr. SHAKESPEARE said that our experience since the introduction of safeguarding had shown that the imposition of a tax did not necessarily mean an increase of price. On the contrary, safeguarding had enabled home manufacturers to produce articles at a steadily falling price. When insulin was first manufactured in this country at the beginning of 1923 the price was 25s. per 100 units. It rapidly fell to 2s. 8d. Imported insulin was made subject to the general 10 per cent. duty until 1933. Two firms in this country were, in 1933, producing it at 2s., and the third firm at 1s. 8d. per 100 units retail price. The retail price of imported insulin was 1s. 5d. After the inquiry was held, it was decided that insulin was really a fine chemical, and the result of the imposition of the 33½ per cent. duty was that there had been a reduction of the British price; instead of 2s. per 100 units, two firms were now producing it at a retail price of 1s. 10d. A third firm was actually retailing it at 1s. 5d. per 100 units. The price of the imported product had not risen, in spite of the duty, but remained at 1s. 5d. per 100 units. Insulin was cheaper in this country, probably, than in any other country in the world, except, possibly, Scandinavia. Quite recently representations were made by American and Canadian producers to British producers that if the price was reduced any more it would be impossible to compete and produce at an economic level. Only a few months ago the price of the American article was 4s. 9d. per 100 units, compared with 1s. 10d. Commander Locker-Lampson, intervening, asked if it could not be got for 6d. in Denmark. Mr. Shakespeare replied that the retail price from Denmark was 1s. 5d. The hon. member was perhaps thinking of the fact that, apart from this retail price, insulin was supplied by a British firm at 1s. per 100 units to all the hospitals, and every person suffering from diabetes who was an insured person got insulin free. In view of the fact that the Americans could not produce it at anything like our price, and that it was cheaper here than anywhere, except Scandinavia, he could see no reason for the apprehensions of the hon. member. One could only hope that the stabilization of the duty would enable the home producers of insulin to do what other producers had done, and, by a reorganization of production behind the duty, and with an assured market, steadily to reduce the price of the commodity. There were reasons why Denmark, with her strong organization of the pig industry, could produce insulin more reasonably than other people. The Minister of Health was watching the matter, and there was no cause for apprehension. On the contrary, we could congratulate ourselves that, in spite of the duty, the price had fallen, and was falling.

Insulin Manufacture under Licence.—Sir HILTON YOUNG told Commander Locker-Lampson, on February 8th, that insulin was manufactured in the United Kingdom under licences granted under the Therapeutic Substances Act, 1925, subject to compliance with the regulations made under the Act. He did not think that any was made by the Government. Commander Locker-Lampson gave notice that he proposed to raise the subject shortly on a motion for the adjournment of the House.

Dangers of Oxy-acetylene.—Mr DOUGLAS HACKING told Mr. Dingle Foot, on February 14th, that new legislation would be required to extend to ships being repaired in wet dock the regulations concerning oxy-acetylene apparatus. He had no reason to think ship-repairing firms did not take similar precautions when using oxy-acetylene apparatus, whether the ships were in a wet or a dry dock. The Shipbuilding Employers' Federation was circularizing its members on the special dangers revealed by a recent fatality at Millwall and on the precautions necessary.

Rehousing in London.—In reply to Major Nathan, on February 15th, Sir HILTON YOUNG said it was estimated that about 15,000 persons living in the county of London would be displaced and rehoused during 1934-38 by the combined operations of the London County Council and the metropolitan borough councils. The number of persons to be displaced and rehoused by local authorities wholly or partly in the metropolitan police district but outside the administrative county area was estimated at about 19,000.

Protection from Poison Gas.—On February 20th Captain GURST asked whether any education of the masses was being undertaken to instruct how they should behave in case of gas attack from the air. Mr. RAMSAY MACDONALD referred to a reply given on November 23rd last year by the Home Secretary. He added that the problem of protection had engaged the attention of successive Governments, and precautions were being taken to safeguard the civil population as far as possible against air attack.

School Medical Inspection.—Mr. RAMSAY MACDONALD told Sir E. Campbell, on February 15th, that medical inspection of children in elementary schools did not normally extend below the waist or necessitate the entire stripping of every child. In cases where there was reason to suspect the existence of a defect which required a more complete examination, suitable arrangements were made for this to be carried out. He was not satisfied that the advantages of making a complete examination as a routine practice would justify its adoption in view of the objections which might be raised by parents.

Inadequate Slum Clearance Schemes.—Sir HILTON YOUNG, answering Mr. D. G. Somerville on February 15th, said that, as the result of inquiries which he had caused to be instituted into the adequacy of the slum clearance schemes at eleven towns, eight had furnished information necessary for the discharge of his responsibilities in respect of slum clearance under the Act of 1930. He had communicated with the authorities concerned his conclusions on the reports made to him. The report on the inquiry at Bootle was receiving his consideration, and he awaited an inspector's report on the inquiry at Leicester. He was also making further inquiries of the corporation of Croydon.

Diluent of Calf Lymph.—Sir HILTON YOUNG informed Mr. Groves, on February 15th, that the diluent used in the preparation of calf lymph was a mixture containing 50 per cent. of sterilized glycerin and 50 per cent. of distilled water.

Foundling Hospital Site.—Replying to Dr. Howitt, on February 14th, Mr. SUMMERS said the Minister of Health could not promise a Government grant towards the purchase of the Foundling Hospital site.

Prosecutions under the Poisons Act.—Mr. HACKING told Mr. Grenfell, on February 15th, that the Pharmaceutical Society initiated proceedings in Great Britain for breaches of the Pharmacy and Poisons Acts in 170 cases in 1931, in 169 cases in 1932, and in 161 cases in 1933. In addition, the police in England and Wales, who had power to intervene only in cases in which they had reason to suspect a breach of the law, prosecuted in eighteen cases in 1931, and in ten cases in 1932. Figures of police prosecutions for 1933 were not yet to hand. The duty of enforcing the provisions of the Act of 1933 was placed upon the Pharmaceutical Society and the local authorities, according to the classification of the poison in the Poisons List. Both were given full powers of inspection. Hitherto routine inspection had been confined to the Pharmaceutical Society, with undoubtedly inadequate powers. The new Act considerably increased those powers, but had not yet come into force, and the House must wait to see whether those powers were sufficient.

Evasion of the Medicine Stamp Duty.—Mr. HORE-BELISHA said, on February 15th, that he knew certain manufacturers of medicines had taken steps, one being a disclaimer of proprietary rights, to bring their preparations within the scope of the exemption from Medicine Stamp Duty. He had noted a suggestion of introducing a penny stamp for such packages, if of small value.

Notes in Brief

The Prime Minister states that it is not yet possible to fix a date for the introduction of the Housing Bill.

Medical News

Sir George Newman will deliver four lectures, illustrated by lantern slides, on Florence Nightingale and hospital services, at Gresham College, Basinghall Street, E.C., on February 27th and 28th and March 1st and 2nd, at 6 p.m. Admission free.

The Hunterian Oration will be delivered before the Hunterian Society at the Mansion House, E.C. (by kind permission of the Lord Mayor), on Monday, February 26th, at 9 p.m., by Dr. B. T. Parsons-Smith, on "Cardiac Failure in the Eighteenth Century and its Modern Conception."

The Council of the Metropolitan Counties Branch has invited the recently qualified and all fifth- and fourth-year students to an address and cinematograph display by Dr. R. G. Canti, on "The Cultivation of Living Tissues," on Tuesday, March 6th, in the Great Hall at B.M.A. House. Tea will be served after the guests have been received by the president of the Branch, Dr. Chas. F. T. Scott, at 5 p.m.

At a drawing-room meeting, on behalf of the Institute of Ray Therapy, Camden Town, N.W., to be held at the Mansion House on Friday, March 2nd, at 3.30 p.m., the speakers will include Lord Horder, Sir William Hale-White, Sir Robert Stanton Woods, and Dr. W. J. O'Donovan.

The 160th anniversary dinner of the Medical Society of London will be held on Tuesday, March 6th, at the Trocadero Restaurant, at 7.30 for 8 p.m., with the president, Sir John Thomson-Walker, in the chair.

A dinner in aid of the Metropolitan Hospital will be held at the Savoy Hotel on Wednesday evening, February 28th, when Lord Moynihan will be in the chair. Particulars can be obtained from Mr. G. Cooling, secretary, Metropolitan Hospital, Kingsland Road, E.

The Royal Sanitary Institute has arranged a sessional meeting at the Central Middlesex County Hospital, Acton Lane, Willesden Junction, N.W., on Saturday, March 10th, at 10 a.m., when a discussion on "Maternity and Children's Hospitals" will be opened by Mr. A. Saxon Snell, F.R.I.B.A., with Dr. George F. Buchan in the chair. After the discussion members will be conducted over the new children's wing of the hospital. Professor James A. Donll, M.D. McGill, D.P.H. Lond., Western Reserve University, Cleveland, Ohio, has been elected an Honorary Fellow of the Institute.

The annual general meeting of the Medical Officers of Schools Association will be held at 11, Chandos Street, W., on Friday, March 2nd, at 5 p.m., when there will be a discussion on the necessity for greater reciprocity between parents, consultants, home doctors, and school authorities, more especially in matters relating to health, to be opened by Sir Montague Foster and Dr. H. C. Cameron. Tea at 4.30 p.m.

Some two years ago Sir G. Buckston Browne, F.R.C.S., offered to present to University College Hospital Medical School a number of valuable pictures and articles of furniture from his collection in Wimpole Street. It was suggested to him that a common room for the senior staff would be an appropriate place in which to house his handsome gifts. Sir Buckston Browne fell in with this idea, and the room was finished and formally opened in July last. A descriptive catalogue of the pictures and furniture has now been compiled by the donor, and is printed in pamphlet form, together with a portrait and brief biography.

To honour the occasion of his approaching marriage, Dr. M. J. Nolan, resident medical superintendent of Down County Mental Hospital, was presented by the consultant and resident staffs of that institution, on February 9th, with a radio-gramophone. Dr. Nolan is a consulting visitor in lunacy to both the Lord Chief Justice of Northern Ireland and to the Chief Justice of Southern Ireland. He is also a justice of the peace for County Down.

The Fellowship of Medicine and Post-Graduate Medical Association (1, Wimpole Street, W.) announces that the seventh lecture-demonstration, by Dr. Clark-Kennedy, on jaundice, will take place at the Medical Society of London on Tuesday, February 27th, at 2.30 p.m. The subject of the eighth lecture, on March 6th, will be anaemia. A demonstration on the treatment of recent and old fractures will be given on February 27th, at 2.30 p.m.; by Mr. Alan Gairdner, at the St. George-in-the-East Hospital. A whole-day course in medicine, surgery, and gynaecology will be given at the Royal Waterloo Hospital, March 5th to 24th; a course in orthopaedics at the Royal National Orthopaedic Hospital, from March 5th to 10th; and an all-day course in proctology at the Gordon Hospital, from March 5th to 10th. Courses of instruction arranged by the Fellowship of Medicine are open only to members and associates.

The German Society of Internal Medicine will hold its forty-sixth congress at Wiesbaden from April 9th to 12th, under the presidency of Professor Schittenhelm-Kiel. Joint sessions are being arranged with the German society for the study of diseases of the digestive system and metabolism. Among the subjects to be discussed are the part played by vitamin D in metabolism and digestion, the physiology and chemistry of the sex hormone, normal and pathological ovarian function, the physiology and pathology of nutrition, and the significance and distribution of localization in the nervous system. Further information may be obtained from Dr. J. F. Bergmann, Trogerstrasse 56, Munich.

Two medical tours of the Mediterranean and its vicinity have been arranged for Easter. One, under the patronage of the Marseilles Faculty of Medicine, opens at Marseilles on March 27th, and includes Aix-en-Provence, Cassis, Toulon, Hyères, Saint-Raphael, Cannes, Juan-les-Pins, and Antibes, terminating at Cannes on April 3rd. Extensions can be arranged to Avignon, Saint-Remy, Arles, and elsewhere. The other, sponsored by the Strasbourg Faculty of Medicine, from April 1st to 8th, starts at Cannes and ends at Nice, having included in its scope Antibes, Grasse, Nice, Monaco, Villefranche, and adjacent towns. Further information about these tours may be had from the Federation of the Health Resorts of France, Tavistock House (North), Tavistock Square, W.C.1.

The Departmental Committee which is considering the question whether it is desirable that the law should be altered so as to enable definitions or standards of food to be prescribed held a meeting on February 20th, when evidence was given by Mr. E. W. Cemlyn-Jones, Mr. W. L. Platts, and Lieut.-Colonel T. R. Ubbell, on behalf of the County Councils Association, by Dr. W. G. Savage and Dr. Charles Porter on behalf of the Society of Medical Officers of Health and the Association of County Medical Officers of Health jointly, and by Professor J. C. Drummond and Dr. W. M. Willoughby on behalf of the People's League of Health.

Ever since the British Red Cross Society's Blood Transfusion Service has been in existence there has been difficulty in keeping the individual members together as an organization. Living widely apart, some as far as fifty miles from London, and possessing no interest in common beyond the anxiety to be of service to suffering humanity, there has been a lack of cohesion that has been felt in far too frequent droppings out from the service. The Society has now sanctioned as an experiment for a year the issue of a general circular to members, containing notes of interest, statistical returns, reports of cases, dates of forthcoming lectures and social gatherings, and answers to questions often raised in connexion with the technical side of blood transfusion.

Mr. F. W. Hampshire, chairman and managing director of the well-known firm of manufacturing chemists of Derby, has promised the sum of £35,000, spread over seven years, to the fund which University College Hospital is raising in celebration of its centenary.

The address by Dr. H. L. Gordon on "Amentia in the East African," of which a report appeared in these columns on November 18th, 1933 (p. 923), has now been published in full in the *Eugenics Review*.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, *Aitology* Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate* Westcent, London.

MEDICAL SECRETARY, *Mediscra* Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Chronic Gonococcal Infection

"PERPLEXED" asks for suggestions on the following case: A male had gonorrhoea eighteen years ago. Two years ago he came to me with a very slight urethral discharge. Since then I have constantly been treating him with irrigations of pot. permang. and of zinc permang., injections of autogenous vaccine, capsules of santal-wood oil, caprokol, pyridium, and also massage per rectum. In spite of all, smears taken every now and then show the gonococcus.

Treatment of Chronic Herpes

Dr. R. W. H. TINKER (Painswick, Glos.), in reply to the query of "Vesicle" in the *Journal* of February 10th (p. 268), writes: May I suggest that he should try pituitrin injections if he has not already done so? During the last six months I have been treating all herpes cases with daily doses of five international units of Messrs. Duncan and Flockhart's pituitary (posterior lobe) extract. Most cases have only required one or two doses, and the maximum number I have had to give has been four. The effect of this treatment is astounding. Not only is the pain rapidly controlled, but the lesions themselves quickly disappear. I have rough notes on most of these cases, whose ages range from 40 to 84, and pregnancy seems to be the only contraindication.

Dr. HERBERT J. GREEN (Banff) writes: I have found that auto-injection of 25 c.cm. of the patient's whole blood injected deep into the gluteus muscle, along with small doses of calomel, has the most dramatic effect in a very resistant case of herpes. A slight pyrexia results, causing little discomfort, but the reaction seems to have the desired effect. I first saw this treatment advocated by Dr. Roxburgh, in his book *Diseases of the Skin*.

"W. H. B." writes: I would suggest trying filtered doses of x rays over the site of the lesion. The dosage suggested is one skin unit through three millimetres of aluminium every fortnight for three applications, and a fourth application three weeks thereafter. I cannot explain its action, but I have seen beneficial results in similar cases.

Income Tax

"Child Allowance"

"R." has a son, 21 years of age, who has been a pupil at a school of chiropody. A premium has been paid, and the son is required to study for a year at least. The "child allowance" has been refused on the ground that the school in question is "not a recognized educational institution."

** The question is governed by Section 21 of the Finance Act of 1920. Subsection (1) requires that the "child" shall be receiving full-time instruction at any university, college, school, or other educational establishment, and Subsection (4) provides that "if any question

arise the Commissioners of Inland Revenue may, on request of the Income Tax Commissioners concerned, consult the Board of Education." Taken as a whole the section appears to contemplate general rather than vocational education, at least unless the vocational training is in connexion with a recognized university, etc. If it has not already been done, we suggest that "R." should send up the prospectus, etc., of the school of chiropody in question to Somerset House and ask for a specific ruling—or perhaps the school, being indirectly interested, would take the matter up for him. If that decision is adverse, it is probably useless contesting the point further.

Tax on Interest Received: Repayment

"TINTAX," in a letter supplementary to that summarized in our issue of January 20th, page 131, asks what repayment he can claim.

* The income liable to assessment and allowances due are as follows:

Interest, £197 + £10	£207 0
Annual value of house...	£54 0
						£261 0
Allowances due:						
Personal	£150 0
"Child"	£ 50 0
Dependent relative	£12 10
						£48 10

Tax chargeable at 2s. 6d. on £48 10s. amounts to £6 1s. 3d.

As against this "Tintax" has paid at 5s. in the £ on the remainder of his income—that is, he has had the "relief" at 2s. 6d. in the £ on the above £48 10s. only. He is therefore entitled to repayment on £175 - £48 10s. = £126 10s. at 2s. 6d. = £15 16s. 3d. less the £6 1s. 3d. payable direct—that is, to a net repayment of £9 15s.

Replacement of Car

"OCTAVIUS" paid £325 for a car five years ago. He is now selling it for £65 and buying another for £318. He has made no claim for depreciation in the past. What can he claim now?

* He can claim as a professional expense of the year in which he buys the new car the amount of the actual out-of-pocket cost—that is, £318 - £65 = £253. If he makes his accounts up to March 31st, for instance, it will reduce his profits for the year ending at that date and his assessment for 1934-5; if, on the other hand, the usual ending date of his accounts is December 31st, then the transaction will reduce his profits for 1934 and will affect the assessment for 1935-6.

Professional Premises—Part Sublet

"DOUBTFUL" used to rent a lock-up surgery. He has since taken larger premises, sublet a part, and uses the other part as his surgery. How should the rent received by him be dealt with for income-tax purposes?

* "Doubtful" may adopt one of two alternatives: (1) treat the rent received as professional receipts and deduct the whole of the rent, rates, etc., paid for the premises as professional expenses; or (2) divide the expenses into two parts by estimating how much applies to the sublet portion, and exclude the rent receipts and the relative part of the expenses. The former alternative is simpler, as it avoids the necessity for estimating the ratio between the two portions.

Salary Inclusive of Board and Lodging

"S. B." receives £350 as resident medical officer at a hospital, but, instead of being provided with rooms and board, receives a further £150 and the use of a small house. The previous M.O. was under a different arrangement, and had to pay tax only on his salary.

* "S. B." is liable to assessment on the £350 + £150 = £500. The difference in taxation as compared with his predecessor may seem to him unfair, but "S. B." is in the same position as the great majority of salary earners—his predecessor was in the smaller but fiscally more fortunate group who receive benefits tantamount to an addition to income but in a form which leaves them free from assessment.

LETTERS, NOTES, ETC.

Surgery of the Biliary Tract

Mr. MAKHAN SINGH KHERRA, F.R.C.S.Ed. (surgeon to the Machwi Mines, Ltd., Burma), writes: In the recent correspondence on biliary lithiasis in the November issues of the *Journal* there are two opinions as to treatment: (1) removal of the gall-bladder, and (2) external drainage. The first stands on the grounds that drainage is inefficient in the treatment of gall-stones, and the latter that the removal of the gall-bladder is a serious procedure. I enclose a reprint of my paper which appeared in the issue of the *Indian Medical Gazette* for October, 1933, where I stated my opinion that the *via media* between the two operations is anastomosis of the gall-bladder to the second part of the duodenum in a normal stomach, and to the stomach in the case of an active stomach. My reasons are laid out in that paper, and I shall welcome the opinions of your readers on the subject.

Barbiturates and the Poisons Regulations

Mr. N. E. MORGAN, M.P.S. (London, N.W.5), writes: May I be allowed to correct Dr. Eric A. Freyworth's statement in the *Journal* of February 17th that dial (diallyl barbituric acid) and other barbituric acid derivatives ought to be included in Part I of the Poisons Act? He will find that Part I of the Poisons Regulations states: "Diethyl barbituric acid and other alkyl, aryl, or metallic derivatives of barbituric acid, whether described as veronal, propional, etc." As dial comes within this designation pharmacists have always considered it a Part I poison. The consumption of these drugs could be greatly reduced if doctors would take the trouble to mark their prescriptions "Not to be repeated."

Textbook Discrepancies

Mr. LIVINGSTONE POW, F.R.C.S.Ed. (Wrexham), writes: It is a notorious fact that one textbook will make a statement which is flatly contradicted by another dealing with the same subject. This, while a source of bewilderment to the young student who has yet to learn how "fluid" oftentimes is medical truth, can frequently enough be pardoned in the case of rare or difficult conditions; but I have recently become aware of a remarkable trio of such statements on such a common question as the incidence of breast carcinoma. They emanate from very recent textbooks, all of which, I imagine, are widely read by the younger members of the profession and by senior students. Two are textbooks of surgery, while the other deals with surgical pathology. They are as follows: (1) *Short Practice of Surgery* (Bailey and Love, vol. i, p. 183): "Women between 40 and 50 years of age who have borne and suckled children are its [breast carcinoma's] most frequent victims, but the disease is not rare in spinsters." (2) *Textbook of Surgical Pathology* (Dick and Ilingsworth, p. 338): "Nulliparae are somewhat more liable to be affected than multiparae, perhaps owing to the frequency of chronic mastitis in the former." (3) *The Science and Practice of Surgery* (Romanis and Mitchever, vol. ii, third edition, p. 475): "There appears to be no difference in its incidence in multiparae or nulliparae, nor does the question of whether the breast has been used for suckling make any difference." On this particular question the above should satisfy even the most broad-minded of students.

Childbirth at 50 Years of Age

Dr. F. W. STANSFIELD (Reading) writes: In connexion with Dr. E. L. Bunting's case, reported in the *Journal* of January 27th, I remember attending a woman in her fifty-first year some twenty-five years ago. She had had a long interval without any children, and was a healthy, muscular woman. The presentation being normal, I gave her plenty of time for a spontaneous delivery, but although she had strong pains for several hours and made vigorous voluntary efforts, she was unable to deliver herself. I applied forceps and delivered her, after a time, of a strong and lusty baby. Both mother and child did well, and neither had a bad symptom.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 37, 38, 39, 40, 41, 44, and 45 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 42 and 43.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 80.

HYPOCHONDRIASIS: INDIVIDUAL, VICARIOUS, AND COMMUNAL*

BY

ROBERT HUTCHISON, M.D., F.R.C.P.

PHYSICIAN TO THE LONDON HOSPITAL AND TO THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET

The term "hypochondriasis" has been defined in various ways, but I propose to understand by it, for the purposes of this lecture, any morbid interest in or over-anxiety about health. Hypochondriasis in this sense may affect an individual in regard either to his own health or to that of those near and dear to him, or it may take a collective form and involve a whole community. These different manifestations may be spoken of as individual, vicarious, and communal hypochondriasis respectively, and my purpose here is to consider each of them separately, and to discuss what our attitude as doctors should be towards the affection.

THE GENERAL HYPOCHONDRIAC

Over-anxiety about individual health may take several forms. Perhaps the commonest type is the general hypochondriac: the man who is always fussing about his health and fears that he is getting, or has already, some disease. Such a patient is usually a man in advanced middle life, generally retired from business, who makes his health his hobby, and who collects symptoms as others collect stamps or old china. Retired-Army men seem to be particularly subject to the complaint, just as they are apt to make a hobby of interpreting Old Testament prophecies or tracing the fate of the lost tribes. In most cases this form of hypochondriasis is harmless enough, but it must be remembered that it is sometimes the beginning of an involutional psychosis, and that he who begins by having delusions about his health may end in delusional insanity. I well remember, for instance, the case of a man who began by walking the streets of London, even in winter, with a stout green umbrella to protect him from sunstroke, and who ended with delusions of persecution.

In the management of such a patient our chief duty is to keep him out of the hands of quacks, of whom he is the predestined prey. To attempt to cure him is useless, and would be unkind if it were possible, for why deprive the patient of his main interest in life? (I say nothing of the unwisdom of killing the goose that lays the golden eggs.) Further, one should never tell the patient that there is nothing wrong with him, for that is the sure way to lose his confidence for ever. Listen to him patiently, examine him thoroughly, reassure him confidently, give some explanation of his symptoms, prescribe a placebo, and you send him away happy—until the next time.

THE NOSOPHOBIC

The nosophobe is a slightly different type of the individual hypochondriac. He is the man who goes in fear of some particular disease—cancer, appendicitis, venereal disease, "blood pressure," or whatever happens to be the particular dread of the day. I remember such a patient a few years ago sitting himself down in my consulting room and, after staring at me lugubriously for a moment or two, hurling at me in a sepulchral voice the devastating question: "Am I damaged goods?" Not

being much of a frequenter of the cinema I was not aware that a propagandist film with that title had been on exhibition shortly before the visit, so I had to ask him what on earth he meant. Needless to say he proved to be quite sound "goods," but even two negative Wassermann reactions by two separate pathologists failed to convince him of it, so deep-rooted was his syphilophobia. He was a good example of the fact that nosophobia is apt to result from health propaganda acting upon an anxious temperament—a fact which enthusiastic health propagandists would do well to note. I am told, to take another example, that nowadays when "health talks" on maternal mortality are being widely broadcast many young married women are contracting a morbid dread of childbirth, a new form of phobia for which someone will no doubt soon invent a name. It must be remembered, however, that just as general hypochondriasis may be a manifestation of a psychosis so may nosophobia, and I have known of more than one sad example of a man beginning with the delusion that he had cancer or syphilis and ending in a madhouse. In dealing with such patients all we can do is to try to persuade them by the most thorough examination that their "fears are liars," and to this end special methods such as x-ray examination or laboratory tests, even when unnecessary—may be more convincing than the ordinary clinical procedure.

But it is more in the prevention than in the cure of such cases that we doctors have a responsibility. I have spoken of the share of health propaganda in their creation, and I shall have something more to say about that later on, but individually we have much to answer for, because by shadowed hints about a "grumbling appendix," a "slightly raised" blood pressure, a "flabby" heart, or a "suspicious" apex, the seeds of nosophobia are implanted in many patients, never again to be eradicated.

THE CRANK

The third variety of individual hypochondriac is the crank or health faddist: the man who believes that health is only to be attained by following some special rule of life. The particular fad varies from year to year. Often it is dietetic, and health is only to be secured by drinking sour milk, by eating raw vegetables, by abstaining from salt, by taking in vitamins, and so forth; or fresh air and deep breathing are the panaceas, or, as recently, dress reform, or lying in the sun with little or no dress on at all.

In our management of cranks it is well to remember that there is "something in" most fads, and that they are often only virtues pushed to excess. Argument is of no use in such cases, but ridicule is sometimes effective, though it must be applied to the mass and not to the individual. On the whole, unless the crank is actually doing himself harm by his practice, he is best left alone, and after all he often contributes to a grey world an element of comedy for which we should be thankful. But here again we cannot divest ourselves of all responsibility, for almost every one of these "cranks" can claim some medical authority for what he does, and it will be time to deal with the laity when we have purged our own profession of faddery, especially among those of us who undertake to enlighten the public on health matters in the daily Press.

* A British Medical Association Lecture delivered before the St. Pancras Division, October 10th, 1933. Part of the material in this lecture was also used for addresses before the Harrogate Medical Society and the Oxford Medical Society; and, in a more popular form, in an address on "The Pursuit of Health" at the British Medical Association Meeting at Winnipeg in 1930, afterwards published in the *Canadian Medical Association Journal*, 1931, xxi, 1E.

THE PHYSICAL PRIG

Last among individual hypochondriacs are those whom we may designate physical prigs as opposed to the moral and intellectual varieties of that species. These are mostly young men with an exaggerated standard of health and well-being, who wish, as I have seen it put, to be "utterly fit," and who seek to attain their ideal through exercise, of which in time they become addicts. We do not, as doctors, have much concern with this class of hypochondriac, although as citizens we may agree with *Punch* that "if the whole of England were to concentrate to-morrow on being fit the result would be far more terrible than a general strike."

It is competent for us, however, to ask whether, even from the health point of view, the maximum of muscular development is a good thing to aim at, and whether athletes are sounder "lives" than other people. Every doctor has known young men who have become exercise addicts at school or the university, and who, when they have settled to work in a large town and could no longer get the amount of exercise to which they are accustomed, have suffered in health in consequence. I would suggest, therefore, that as a profession we should encourage the movement towards a more scientifically directed physical education for the young which aims at the harmonious development of the whole body, and discourage a lopsided athleticism; but when the middle-aged man takes up exercise with enthusiasm, or tries to do "physical jerks" to the wireless, it is time that we put in a word of warning in the interest of his heart and arteries.

PARENTAL HYPOCHONDRIASIS

We may turn now to the case of those people who are over-anxious, not about their own health, but about the health of others—the vicarious hypochondriacs. The commonest example is the parent who is over-anxious about his children, but one also finds many among unmarried daughters who are fussy about the health of an aged parent. The wife who has a husband much younger than herself is also apt to be vicariously hypochondriacal about him, although, curiously enough, one does not often meet the young husband who is over-anxious about the health of an elderly wife.

Parental hypochondriasis has now become almost a national danger partly because, no doubt, children, like the Sibylline Books, have become dearer as they have become fewer. Over-anxiety begins almost from the word "go," for no sooner has the *anti-natalist* allowed a child to be conceived than the *ante-natalist* gets busy; the infant is surrounded by an atmosphere of fuss while still in the womb, and the birth is anticipated as a major operation fraught with terrible possibilities both to the child and to the mother. Arrived in this vale of tears, the child falls into the hands of a "scientifically trained" nurse, who considers it her duty to disregard his wailings to be comforted and to make all his infant routine as regular as the movements of the planets. From her care he may pass to that of a welfare centre, where he is weighed and measured and physically criticized week by week, or, if born in a higher sphere, he is made over to the ministrations of a paediatrist, who measures out his meals with the meticulous nicety of an analytical chemist, and plies him assiduously with orange-juice, glucose, and fish-oil. During the "pre-school" age, however, he has a short respite, and may, if lucky, come under the maternal care of an old-fashioned nanny, and it is an ironical fact worth pointing out that this is the very period of childhood at which mortality has fallen most sharply in recent years. But soon, in the lower

classes at least, he passes into the clutches of the school medical service, and he has hardly escaped from that when he becomes a panel patient, with the right to call in a doctor freely for the most trivial symptoms, and by that time he is fully qualified to be an individual hypochondriac on his own account.

Among the so-called *intelligentsia* parental hypochondriasis is even worse. Not content with keeping a progress book in which the child's physical development is noted down from day to day, the mother is apt, with the aid of an elementary treatise on psychology, to insert clumsy fingers into the delicate mechanism of the child's growing mind, while at the same time she vicariously applies to his body any fad of diet or management which happens to be the fashion of the moment. Apropos of this subject I read some years ago an article entitled "The Antiseptic Baby,"* the first paragraph of which was as follows:

"I hold no brief for the good old days—at least, so I supposed until I saw Philip in his basket. Basket, however, is hardly the word: bath-tub is more descriptive of a 'washable' white canvas affair surrounded by a washable screen to shut out the draughts. Philip's small person was covered with white washable porous woollen. He was dressed in soft woollies, light, absorbent, and easily-laundered. His nursery was painted with white washable paint, had bare floor, bare walls, no curtains to take up the dust, no pictures to distract the infant eye, no fire to send out soot, central heating kept at an even temperature throughout the day. I say throughout the day, though how should I or anyone else know it? For no one, except the antiseptic nurse, ever set foot in that nursery during the day. From five o'clock to five-twenty Philip was on view, provided he was not handled or excited."

The writer, after contrasting the very different methods of an old Irish nanny, concludes:

"Yet it was only yesterday that I heard Philip's mother making an appointment with an eminent authority on child problems. 'I am anxious about my son, Philip,' she said over the telephone. 'You know I depend on you. I wish you to advise me how to make him more adventurous.'"

Things are just as bad for children of the boarding-school age. I remember, for example, a boy of 11 whose mother was one of the worst vicarious hypochondriacs possible; her case is typical of many. A private letter from the head master of the preparatory school said:

"By to-morrow the boy will have seen eight doctors in the last two months. We do not doubt his having had asthma at home, and we think it probable that he has an unhealthy appendix and that an operation may be necessary, but we think you ought to realize that Mrs. — is so over-anxious about the boy's health that there is a risk of her making him into a physical and moral wreck. The boy, at present, takes every opportunity of feeling as well as his mother allows him to, but he is so trained to regard himself as an invalid that he may not be able to hold out much longer. The following are the instructions she sent to us with regard to his daily regime:

Colds. Avoid all chance of colds when possible. Go to bed directly a cold begins, and stay there until the cold has gone. Special prescription to be given if a cold starts.

Spray. A new solution. To be used after breakfast, lunch, tea, and senna pods. Three times each nostril, twice on throat each time.

Pains in head. Assigned to bromide medicine, or neuralgia. Pains in stomach. To be watched for appendix trouble.

Not to have bromide, potatoes, starchy food, spinach, bread, pastry, fruit with pips.

Not to swim. Not to go out before breakfast. To have one teaspoonful liquid paraffin before breakfast, lunch, tea; seven senna pods; warm water before breakfast; flat-foot exercises; one and a half teaspoonfuls bicarb. soda after lunch; two sticks of barley sugar.

* *Norland Quarterly*, August, 1927.

To put on coat or sweater directly after exercise.. To avoid dust.

Temperature to be taken night and morning.

So afraid, too, is the modern parent of "microbes" that children are carefully shielded from all possible contact with infection, with the result that they fail to get the ordinary infectious illnesses at the safest age, 5 to 10, but contract them later on, often in a much severer form and at a more inconvenient time. Any medical officer of a public school will confirm this.

You may say that child mortality has fallen greatly in recent years. True, though it is doubtful to what extent all this fuss and over-anxiety are responsible for the fall; but, mortality apart, how about morbidity? Are children really any healthier than they were? Are they as full of vitality? Are they, in a word, as good animals? I gravely doubt it. More and more the modern child seems to me to suffer from lack of appetite, from poor digestion, and from unstrung nerves, and what I am convinced he needs above everything else is more neglect.

Now what should be our attitude as doctors to all this parental hypochondriasis? It has gone too far, I fear, to be stopped altogether, but at least we might refrain from adding to it by giving people the impression that the rearing of a healthy child is a task of superhuman difficulty. When we meet it in the parents of children for whom we are professionally responsible great tact and self-control are required. It is fatal to give the mother the impression that one thinks her "fussy" or "spoiling," since in that case she will simply go elsewhere. All one can do is to be as complaisant as one can, to give in or to moderate when the fad is unimportant, and only to forbid when it is likely to do definite harm to the child's mental or physical health.

FILIAL HYPOCHONDRIASIS

But vicarious hypochondriasis also occurs at the other end of life, and we see every day old people being fretted and fussed by the well-meant anxiety of others for their health. (Father must not go out for fear of bronchitis, he must not smoke because it is bad for his heart, he must not play bridge in the evening because it interferes with his sleep, and so forth: you all know the kind of thing.) Here, I think, we should use our influence in favour of the old being allowed to do in reason as they like, even at some risk to their lives. After all, why keep them lingering superfluous on the stage, and, if liberty to do as they like makes them happier, may it not on that very account make them healthier as well? And surely to try to prolong life merely for the sake of living is no very worthy ambition.

COMMUNAL HYPOCHONDRIASIS

Finally, over-anxiety about health may affect a whole community. It is true that this attitude of mind has not yet, fortunately, got much hold upon the people of this country, though it seems to be rampant in America, but there are plenty of agencies at work even here whose object is to produce what is termed a "health conscience," but which is better termed "disease consciousness." We all know by what methods of lectures, talks, leaflets, and slogans they set about the work, and those of you who saw Jules Romains's amusing comedy *Dr. Knock* a few years ago will realize how easily such methods may succeed in infecting a community with hypochondriasis. Our legislators also take a hand in the game of demoralization, for how many hypochondriacs have the Workmen's Compensation Act and the National Insurance Act, to take only two instances, produced? The morbidity statistics of insured persons provide the answer.

INDIVIDUAL HEALTH PROPAGANDA

Now what should be our attitude as doctors to all this? I think we must first distinguish clearly between environmental hygiene and individual health propaganda. The former is the business of the public health service, and must command our full support and co-operation. Individual health propaganda, however, is in a totally different category. I believe it to be both useless and mischievous. It is useless because there are no general rules of health of universal application, but only the one old rule of moderation in all things—even in being moderate—and doctors are the last people on earth to observe it. And health propaganda is mischievous for the reason I have already given, that while it runs like water off a duck's back in the case of the healthy-minded, it creates nosophobia wholesale among the anxious. Attempts are constantly being made to rope in the practitioner in this work. He is told that his teaching and practice must be made more "preventive," and that he does not detect disease early enough. As to this matter of early detection I believe there is a lot of nonsense talked. To listen to some exponents of the doctrine one would think that it had descended from heaven as a special inspiration in the neighbourhood of St. Andrews only a few years ago. That, of course, is a delusion. Doctors have always been trying to detect the beginnings of disease, and I well remember as a student many years ago how the importance of the early diagnosis of pulmonary tuberculosis and of cancer was rubbed into us. The trouble, as every clinician knows, is that disease can hardly ever be detected until it has begun to produce symptoms, and not always with certainty even then. "Oh, but," it is said, "if people were periodically inspected every few months a lot of unsuspected disease would be discovered." Would it? I am very doubtful. How many cases of unsuspected cancer, for instance, are revealed by examination for life assurance? And suppose that you do detect a slightly raised blood pressure, say, in an otherwise healthy man, what are you going to do about it? Advise him to give up his livelihood and lead a sheltered life? And by telling him about his blood pressure will you not create an anxiety which will tend to drive it up still higher? No; I am convinced that the amount of early disease which would be detected by periodic examination is negligible, and that it would be more than offset by the amount of nosophobia that would be created by it.

And as regards prevention, surely every doctor worth his salt has always been doing all he can to prevent disease. When in charge of a case of illness does he not do everything to guard against complications and sequelae? When consulted does he not impress upon the patient such rules of health as seem applicable to his special case? Does he not do all that can be expected of him if he gives advice to individuals how to maintain their health as he has opportunity, and if he encourages them to come to him for examination as soon as they feel anything wrong? Of course, if the practitioner had a larger share in the public health services he could do more in the way of prevention, but that line of approach is often closed to him.

In conclusion one may ask, To what is the prevalent and increasing hypochondriasis due? I believe it is largely the result of causes over which we, as a profession, have no control—of the philosophy of the age in which we live, and especially of an exaggerated fear of life and a decay of belief in a Divine providence. Be that as it may, it is surely our duty to use our influence both with our patients and with the public not to yield to it, and to urge them rather, in the words of Robert Louis Stevenson, to stop their cars against paralysing terror and to run the race that is set before them with a single mind.

THE SIGNIFICANCE OF MONILIA IN THE SPUTUM

BY

BERTRAM H. JONES, M.D., M.R.C.P.

PHYSICIAN TO OUT-PATIENTS, CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS, VICTORIA PARK; ASSISTANT PHYSICIAN, PRINCE OF WALES'S GENERAL HOSPITAL, TOTTENHAM

During the last twenty-five years numerous investigators have noticed the association of chronic diseases of the chest with the occurrence of monilias in the sputum, and although much work has been done from the clinical, pathological, and experimental aspects, there is still considerable doubt as to the relation between the organism in the sputum and the concurrent respiratory disease.

Monilia are classified by Hans Zinsser in his *Textbook of Bacteriology*¹ under the heading of Hyphomycetes or Fungi Imperfecti, and the definition reads as follows:

"Monilia.—This name is applied to organisms which appear in the tissues or recently isolated cultures as round or oval cells which reproduce by budding. In older cultures and sometimes in the tissues they show a primitive mycelium made up of elongated cells or long coarse filaments. The absence of ascospores differentiates them from the saccharomycetes or true yeasts."

MONILIA AND LUNG DISEASE

For a time monilia infection of the lungs was regarded as a disease of countries with a hot and moist climate, but cases have now been described in many parts of the world, and the condition can therefore no longer be regarded as a tropical disease. Castellani² found that the workers in tea factories in Ceylon were apt to develop respiratory disease, the manifestations varying from a mild bronchitis to an illness simulating phthisis, in that cough, expectoration, haemoptysis, and emaciation were among the symptoms in severe cases. This series is unique, for the investigator not only demonstrated the fungus in the sputum, but also found it in the tea dust; moreover, in many cases the symptoms abated when the patients were removed from their work. Ellman³ demonstrated a case in which the clinical appearances suggested a diagnosis of pulmonary tuberculosis, but examination of the sputum showed the disease to be due to a monilia infection, and the patient improved on being treated with large doses of potassium iodide. Similar cases have been reported by Stokes, Kiser, and Smith.⁴

Asthma and bronchitis associated with monilia in the sputum have been described by Steinfeld⁵ and by Oliver.⁶ In both series considerable benefit was obtained when the patients were treated with monilia vaccines and large doses of potassium iodide, and Oliver notes that as the condition improves the organisms disappear from the sputum. Beneficial results from the use of a vaccine were obtained by Pijper,⁷ in the case of a patient suffering from cough, copious expectoration, and loss of weight. In this case the sputum contained large numbers of monilia, which were still present after the mouth and pharynx had been washed with a sterile solution. In a later communication Pijper⁸ expressed the view that "vaccine treatment of cases proved satisfactory in a few instances only." In a series of one hundred cases of supposed pulmonary tuberculosis occurring in Bangkok, Mendelson⁹ found that 5 per cent. were due to mycotic infection of the lungs, and at post-mortem examination the lungs were studded with numerous small white masses, some being as large as filberts. On microscopical section these masses were found to resemble somewhat those present in tuberculosis, but they differed in that there

was no caseation and no abscess formation, and the fungus could be seen in the lesion. In England a series of six cases were recorded by Joekes and Simpson.¹⁰ In the milder forms bronchitis was present; in others the signs were those of bronchopneumonia, although the general health was but slightly impaired, and in the more severe cases marked wasting occurred and the signs were suggestive of pulmonary tuberculosis. One of these cases proved fatal, and at the post-mortem examination small white nodules were found to be scattered throughout the lung tissue. Unfortunately no examination was made to prove that these nodules were due to monilia. The pathological changes produced in the lungs as the result of blastomycotic infection occurring in two cases have been described by Medlar¹¹ and Millar.¹² In one case the lungs were the site of a caseous pneumonia with numerous small cavities, and in the other case the presence of firm, white, pearly nodules without caseation and cavitation was found. This latter case was thought to be due to tuberculosis, but microscopical section showed that the lesions were due to a fungus in both cases. Pulmonary tuberculosis is sometimes complicated by the presence of yeast-like organisms in the sputum, and Ferris¹³ described a case of this nature, but concluded that in his case the yeast-like organisms were "secondary invaders of low virulence to animals and low, if any, pathogenicity for man."

ITS OCCURRENCE IN THE SPUTUM

In the ordinary routine examination of the sputum monilia are not commonly found, but if special methods of cultivation are employed they can be demonstrated in quite a high proportion of specimens. Pijper⁴ examined a series of sputa from sixty-seven consecutive cases, and, by using a special technique for staining the films, was able to identify the organisms with ease in seven cases, and also, after a careful search, in nine other cases. By cultural methods he found monilia to be present in as many as thirty-six of the specimens.

Marett¹⁴ has made it a practice for many years to examine all the specimens of sputum submitted to him for these organisms, and during the five years ending 1931 he made nearly two thousand such examinations. Monilia were present in 75 per cent. of the specimens, and he has come to the conclusion that this organism plays an important part in the production of chronic lung infections, and that bronchiectasis may in some cases be caused by this type of fungus.

One method of determining the pathogenicity of an organism found in the sputum is to treat the patient on the assumption that it is the cause of the disease, and to draw conclusions from the results obtained. Marett and Oliver, using this method, have treated their cases with monilia vaccines and large doses of an alkaline potassium iodide mixture, with the effect that many cases have been cured, and the majority have been improved. They are of the opinion that, when monilia are present in the sputum, the patient is suffering from bronchomonilliasis. A second method is to reproduce the lesions in experimental animals and to recover the causal organism from the lesions found. Wade¹⁵ found that subcutaneous injections of a bouillon culture of *Blastomyces dermatitidis* into a monkey caused chronic disease in the lungs with cavitation, and he was able to demonstrate the causal organism in the resulting lesions. Using the organisms grown from the sputum of their cases, Stovall and Greeley¹⁶ obtained comparable results in their experiments on white rats. Joekes and Simpson¹⁰ were unable to produce any pathological lesions in rabbits when the monilia obtained from their patients was used in similar experiments, but were successful when a moderately turbid emulsion of *Monilia pinoyi* was injected intravenously.

Castellani¹¹ is of the opinion that "the mere presence of a monilia fungus in the sputum should never be considered sufficient to establish the diagnosis of primary bronchomoniliasis," and that the production of septicæmic manifestations in experimental animals should not be regarded as evidence that the organism is capable of producing respiratory disease in man. The criterion that he regards as diagnostic is the production of a characteristic localized nodular affection of the lungs at the site of inoculation, when the organisms have been inoculated by intrapulmonary injection.

Using monilia obtained from milk and monilia from sputum, Pijper¹² carried out a series of experiments on rabbits, and found that he was unable to distinguish the source of the organism by the changes produced in the animals; nor was he able to make any distinction between the organisms obtained from the sputa in which they were visible in direct films and those found by cultural methods alone. He sums up the results of his investigations in the following words: "Bronchomoniliasis, therefore, either does not exist, or the majority of chronic affections of the respiratory organism must be called bronchomoniliasis."

PRESENT INVESTIGATION

It will thus be seen that there are many cases of pulmonary disease with monilia in the sputum, and that in a few cases the diagnosis has been confirmed by post-mortem examination; but the difficulty is to know whether the presence of the organism in the sputum is sufficient to make a diagnosis of bronchomoniliasis, or whether the presence of monilia can be disregarded. If it can be proved that monilia are not necessarily present in the bronchi when they are present in the sputum the problem is to a great extent simplified, and it was therefore decided to approach the subject from this point of view.

The modern procedure of bronchoscopy is carried out in such a manner that conditions are ideal for obtaining a swab specimen of the bronchial secretion without fear of contamination from the upper air passages. A laryngoscope with a sliding back is introduced over the tongue until a direct view of the larynx is obtained, and then the bronchoscope is inserted through the glottis into the trachea, the sliding portion of the laryngoscope is removed, and the handle readily comes away. Therefore any swab taken through a bronchoscope which has been inserted by this method is taken with precautions similar to those that have been used for obtaining smears from the post-nasal space or the uterine cervix. This method has been used by Chevalier Jackson¹³ as an aid to the diagnosis of pulmonary mycoses, and when he addressed the Royal Society of Medicine in 1930 he expressed his approbation of its value in the following words: "The great usefulness of the bronchoscope in the diagnosis of these conditions is due to the fact that practically all fungi to be found in suppurative pulmonary foci are found also in the mouth. It is therefore difficult, if not impossible, to be certain that the organisms found in the sputum are really from the bronchi."

In the present investigation the cases examined in this manner were in no way selected, apart from the fact that bronchoscopic examination was thought to be necessary for the purposes of diagnosis or treatment. The bronchial swab was taken from such bronchi as were seen to contain purulent secretion or to be pathologically changed; but if no such changes were present it was obtained from one of the lower bronchi, and in every case the specimen was taken prior to the insertion of any therapeutic substance. The swab having been withdrawn from the bronchoscope, it was at once plunged into a tube containing a solution of sterilized malt extract (specific gravity 1040), which was incubated at 37° C. for one week, at the end of which

time subcultures were made on ordinary agar media and on Sabouraud's medium for moulds. This is the technique recommended by Craik¹⁴ and used by Marett.

In the first twenty-five cases examined by this method monilia were absent from the bronchial secretions, and it was therefore decided to continue the investigation. In the second series the sputum was examined as well as the bronchial swab. In the second series of twenty-five cases monilia were found in the sputum in eleven cases and in the bronchi in one case. Thus there appeared to be no relation between the nature of the bronchial secretion and the presence or absence of the fungi from the sputum. For example, in the second series there were nine patients in whom the bronchial secretion appeared to be normal—that is to say, it was not obviously purulent—and yet, of these nine cases monilia were found in the sputum in no fewer than five. In one of the fifty cases examined monilia were found to be present in the bronchial secretion and also in the sputum. This patient was suffering from pulmonary tuberculosis, with a positive sputum, and had a cavity at the right apex, which could not be collapsed by an artificial pneumothorax owing to the presence of an adhesion. The appearance of his bronchial tree was normal, apart from some purulent secretion in the right upper bronchus. There was no evidence of adherent membrane and no other change which might be ascribed to the presence of a fungoid infection that could be detected with the bronchial telescope. From the clinical aspect his signs and symptoms were those of pulmonary tuberculosis, and there was nothing to suggest that he was in any way adversely affected by the presence of monilia in the bronchus.

The results obtained may be tabulated as follows:

Disease	Examination of Swab from Bronchus for Monilia		Examination of Sputum for Monilia	
	No. of Cases Examined	Monilia Present	No. of Cases Examined	Monilia Present
Abscess of lung	14	0	8	4
Asthma	1	0	—	—
Bronchiectasis	13	0	3	1
Bronchitis	3	0	—	—
Fibrosis of lung	3	0	2	1
Pulmonary tuberculosis ...	3	1	2	2
Carcinoma of bronchus ...	6	0	5	1
Simple growth	2	0	1	1
Mediastinal tumour	5	0	4	1
Total	50	1	25	11

CONCLUSIONS

From a review of the literature there can be no doubt that infection of the lungs with fungi of the monilia group does occur, and that the disease can be reproduced in experimental animals; but the cases in which the disease in man has been confirmed by examination of morbid specimens are rare.

Monilia are commonly present in the sputum obtained from patients suffering from respiratory disease.

The finding of monilia in the sputum is not evidence of their presence in the bronchi.

Bronchomoniliasis cannot be diagnosed from the examination of the sputum alone.

This investigation was carried out on the suggestion of Dr. P. Janvri Marett, after consultation with Dr. S. Roodhouse Gloyne, and was made with the kind permission and assistance of my colleagues Drs. Scott Pinchin and Morlock, who took the swabs for me from patients attending

their bronchoscopic clinic. I have also to thank Dr. Gloyne and those working in the pathological department at Victoria Park Hospital for undertaking the bacteriological examinations.

A NOTE ON THE STUDY OF PULMONARY TUBERCULOSIS IN INFANTS AND CHILDREN

BY

G. GREGORY KAYNE, M.D., M.R.C.P.

NOROTHY TEMPLE CROSS RESEARCH FELLOW IN TUBERCULOSIS

Considerable confusion still exists at the present time on the subject of pulmonary tuberculosis in children. The widely divergent views on frequency, type of disease, and prognosis, held by men of apparently equally high authority, may partly be accounted for by the following factors: (1) conclusions based on the observation of different types of material will vary with the nationality and status of the author, who may be a tuberculosis officer, medical superintendent of a sanatorium for children, physician to a general, children's, or chest hospital, morbid anatomist, or finally, a public health statistician; (2) diagnosis depends on the extent of investigations carried out, particularly as regards radiography, searching for tubercle bacilli when no sputum is available (the rule in children), and employing a tuberculin test; (3) the number of diagnoses confirmed or otherwise must depend on the opportunities for performing necropsies; and (4) the features of the "primary complex" or "primo-infection" are by no means universally appreciated.

I have had the opportunity of studying the methods employed by Armand-Delille and Lestocquoy on the vast material available in the children's department at the Hôpital Hérod in Paris. Their scheme seems logical and complete; moreover, it enables pulmonary tuberculosis in children to be studied in a manner impracticable otherwise. It consists of the following features.

1. Enquête Sociale

For every child admitted a complete inquiry is made by a specially trained health visitor into its past and family history, surroundings, and possibility of contact.

2. Clinical Examination

This implies: (a) a physical examination; (b) x-ray films of the chest, both in the antero-posterior and in the lateral or oblique position; (c) a tuberculin test. The von Pirquet test is used here, as it is almost exclusively elsewhere in Paris. While admitting the greater sensitivity of the intradermal test in dilutions of 1 in 1,000 or 1 in 100, the von Pirquet test is considered sufficient for all practical purposes; (d) the search for tubercle bacilli. These are

looked for as a routine in a gastric washout. A suitable-sized stomach tube is introduced in the morning before the first feed, and 80 to 100 c.cm. of warm water (with a trace of sodium bicarbonate) allowed to run in by holding the container about two feet above the child's head; the gastric contents are then siphoned out by lowering the vessel, and examined by a concentration method, and, if necessary, by inoculating a guinea-pig. Armand-Delille and Lestocquoy claim eminently satisfactory results from this method, and consider it no more inconvenient to the child than swabbing the back of the pharynx after a cough, or removing a small piece of mucus during a laryngeal examination.

3. Necropsy with Anatomical Control of X-Ray Photographs

The method employed here is of particular interest, and is the main object of this note. A necropsy is performed automatically on every fatal case unless the parents take the initiative of objecting immediately after death. The usual post-mortem technique employed elsewhere, which consists in detaching the lungs from the heart either in the thorax or after removal from the body and slicing them with a few vertical or radial cuts, may fail to discover small pulmonary lesions; moreover, the true relation of the lesions to the lung and the heart is

FIG. 1.

difficult to estimate. Preliminary hardening of the organs in formalin causes retraction and loss of normal outline, particularly as regards the costo-vertebral and costo-diaphragmatic portions. Accurate comparison of the lesions with the x-ray photographs is therefore impossible. To obviate these disadvantages Armand-Delille and Vibert devised the following technique.

Hollow moulds representing thoracic cages of various sizes are made by pouring plaster-of-Paris into the thoracic cavities after the contents have been removed through a small sternal opening in bodies with unopened abdomens; while the plaster sets pressure must be maintained on the abdomen to retain the convexity of the diaphragm; plaster bandages are applied over these solid blocks, as in the preparation of a plaster jacket, and the mould thus obtained is subsequently varnished with paraffin. A photograph of such a mould is reproduced in Fig. 1. At the necropsy the whole of the thoracic contents are removed *in toto*, cutting the oesophagus and trachea as high as possible in the neck and leaving the diaphragm *in situ*. A little formalin is injected into the trachea, and the whole mass placed in a mould of the appropriate size, where it is kept in position

by inserting on the inside of the mould a very thin layer of cotton-wool. The mould is then immersed in a 10 per cent. formalin solution for about fifteen days. The whole block, which keeps its form extremely well, is easily dislodged afterwards and cut into frontal slices 1/2 to 1 cm. thick with a brain knife. The slices are washed in running water for two days, then immersed in methylated spirit for twenty-four to forty-eight hours, which causes the return of the normal post-mortem tissue colour. To obtain permanent specimens the sections are placed in large Petri dishes filled with the following solution: gelatin, grains 105; thymol, m5; glycerin, 31.75; distilled water, 31.5. Sagittal, oblique, or lateral sections may be obtained in a similar manner.

FIG. 2.—Sketch of x-ray photograph showing left perihilar shadow.

Examination of the sections enables their situation, form, and relation to other parts to be studied accurately, and permits easy comparison with x-ray photographs taken with the same orientation.¹ Two examples may be

given to illustrate the great importance of such a comparison. A good deal has been written about "perihilar tuberculosis." Figs. 2, 3, and 4 explain how an antero-

FIG. 5.—Sketch of x-ray photograph showing shadow of varying density in right lung.

FIG. 6.—Sketch of lateral section of right lung at axis *c d* (in Fig. 5), showing that varying density of shadow is due to superimposition of two areas of similar density.

posterior photograph may easily suggest a perihilar lesion if one only thinks in terms of two dimensions. An antero-posterior x-ray photograph will often show a shadow of varying density, suggesting different types of lesion. Comparison with the post-mortem sections may, however,

demonstrate that the difference in appearance is due to the superimposition of lesions situated at different depths in the antero-posterior diameter, and actually at the same stage of the pathological process (Figs. 5 and 6). It may therefore be pertinent to conclude by stressing the importance of lateral or oblique x-ray photographs in every case of pulmonary tuberculosis.

It is a pleasure to express my thanks to Dr. Armand-Dehille and to Dr. Lestocquoy for their kindness in giving me the opportunity of becoming familiar with their methods, and for the loan of the photograph.

ON THE LACK OF EVIDENCE OF TRANSMISSION BY HUMAN BEINGS OF TUBERCULOSIS DUE TO THE BOVINE TYPE OF BACILLUS

BY

GILBERT WALKER, M.B., CH.B., M.R.C.P.
LATE ASSISTANT MEDICAL SUPERINTENDENT, GLENLOMOND
SANATORIUM, KINROSS

The stimulus for research into the incidence of disease due to the bovine type of tubercle bacillus, and the virulence of that organism for the human subject, was supplied by Koch when, at the Washington Congress in 1908, he asserted that it was less virulent than the human type, and that it had never been demonstrated as a cause of chronic pulmonary tuberculosis in human beings. Investigation has gone on in several countries since that time, and has led to a fuller appreciation of the role of the bovine bacillus in the pathogenesis of human tuberculosis.

The results were summarized in a paper by Griffith and Munro,¹ which also gave an account of ten new Scottish cases of chronic pulmonary tuberculosis due to bovine organisms. Munro, in 1925, began to isolate and type the organisms from every case admitted to the sanatorium with tubercle bacilli in the sputum, and this work is still going on. For the past two years I have been privileged to assist in this, and am indebted to Dr. Munro for permission to use his figures and clinical notes. Up to September, 1933, 595 Glenlondom strains have been isolated and typed, and of these twenty-three proved to be bovine, while in one case a mixture of bovine and human type bacilli was found, giving a percentage incidence of bovine type of 4. In addition two bovine strains were isolated from a total of forty specimens examined from Ayrshire. Isolation was effected chiefly by cultural methods, rarely by animal inoculation, and in no case did failure to isolate occur, so that no anomalous virus was missed.

Consideration of the group of cases of chronic pulmonary tuberculosis due to the bovine organism reveals several interesting points, and we are concerned here with only one of these. While they are clinically and radiologically indistinguishable from cases due to human bacilli, there is an apparent epidemiological difference at present unexplained—namely, the complete lack of proof of transmission from one human subject to another. How otherwise it is with tuberculosis due to human type bacilli is well known. It is recognized that the disease is produced as the result of contact, more or less prolonged and repeated, with some source of infection, usually an open case of pulmonary disease, and therefore becomes manifest as a "familial" or, more accurately, a "household" disease. So much is this the case that careful inquiry is always made into the family history with a view to

discovering the source of infection, and when two or more members of a family are found suffering from tuberculosis it is assumed that transmission occurred from one to the other.

It is a matter of some practical importance to ascertain whether, in the case of the bovine bacillus, similar transmission from human to human does occur. There is no apparent reason why it should not, but only examination of a large number of cases and full bacteriological investigation of those which show a family history of tuberculosis can settle the issue. Out of the twenty-four cases in the Glenomond series only four instances occurred in which more than one member of the family suffered from tuberculosis, and in only one of these was an opportunity of full bacteriological examination available. In his series of English cases Dr. W. M. Cumming also had one opportunity to type the bacillus where two brothers were found suffering from open pulmonary disease, and he has kindly allowed me to include notes of that case here. These two cases will be reported in some detail, since they show how presumptive evidence of familial disease due to the bovine bacillus was disproved by bacteriological examination.

CASE I

A female, aged 20, was admitted to Glenomond on January 28th, 1933. Her mother had had treatment (not in Glenomond) in 1931, and her sputum at that time was positive for tubercle bacilli. She died at home in September, 1933. The daughter was said always to have been fit as a schoolgirl, and, apart from scarlet fever at 14, had had no previous illness. From the time she was 7 until she was 16 she went for a holiday every summer to a farm. She began to train as a nurse in 1929, and developed a cough in the winter of 1932. This lasted a fortnight and returned a month later, but she remained at work until the time of her admission to Glenomond. On admission she was found to have a root-spread into the left lung and infiltration in the right upper lobe. The tonsillar glands were palpable, but no other glands were felt. Sputum was positive for tubercle bacilli, and a bovine type organism of full virulence was isolated. When it was realized that this organism was a bovine type, a specimen of the mother's sputum was obtained and a human type organism was isolated.

Bacteriological Examination

Sputum from the daughter was inoculated on Corper's potato and modified Loewenstein's egg medium on January 30th, 1933. The virus was dysgonic. On February 28th, 0.01 mg. of pure culture was injected intravenously into a rabbit of 2,500 grams. Thirty-five days later it was killed when very ill and weighing 2,200 grams. Generalized tuberculosis typical of bovine infection of full virulence was found at necropsy. A dysgonic virus was isolated and grown from the spleen. Sputum was sown on egg medium on three subsequent occasions, and each time a dysgonic virus was isolated. On two tubes sown on April 22nd several heaped-up colonies appeared when the culture was about two months old. One of these was subcultured on glycerinated egg medium, and a moist dysgonic growth resulted. Another colony was lifted off and 0.01 mg. inoculated intravenously into a rabbit of 2,000 grams. Necropsy forty-three days later showed the same picture as previously, except that no prominent superficial tubercles were seen on the kidneys. These examinations were done in order to exclude the presence of human type bacilli. This sputum contained only bovine bacilli.

Sputum from the mother sown on potato and egg medium gave rise to a luxuriant growth typical of human type tubercle bacilli. In order to detect the presence of bovine bacilli, 2 mg. of pure culture were inoculated subcutaneously into a rabbit of 2,510 grams. After fourteen weeks it was killed when apparently healthy, and minimal lesions were found in the lungs. No tubercles were present in the kidneys and spleen. This sputum contained only human type bacilli.

CASE II

This case was investigated by Dr. W. M. Cumming at Bradford City Sanatorium, Grassington, Yorkshire. A miner,

aged 48, was found to be coughing up sputum containing bovine type tubercle bacilli, and the strain was isolated on two occasions in 1932. In February, 1933, sputum from his brother, aged 60, was examined, and yielded a typical eugonic strain. This was inoculated into a rabbit, which was killed when in good health two months later. Necropsy showed the typical picture of human type infection, and the strain isolated from the kidney of the rabbit was also typically eugonic.

CASES WITH PRESUMPTIVE EVIDENCE OF FAMILIAL INFECTION

In the cases reported above there was presumptive evidence of familial infection with bovine bacilli, but this was disproved by complete bacteriological examination, which showed that one member of the family was coughing up bovine bacilli alone and the other human bacilli alone. In addition to these cases there were three instances in the Glenomond series in which two members of the family suffered from tuberculosis, but where bacteriological confirmation was not available.

Case 1.—A female, aged 11, was admitted to Glenomond on May 12th, 1933, suffering from advanced bilateral pulmonary tuberculosis with cavitation. She had a gland abscess in the neck at the age of 2. A bovine organism of full virulence was isolated from the sputum on three occasions. Her mother died of pulmonary tuberculosis at home in December, 1931.

Case 2.—A male, aged 33, was admitted to Glenomond in 1933 suffering from generalized tuberculosis, and died at home in August, 1933. A bovine organism of full virulence was isolated from the sputum. A brother died at home of pulmonary tuberculosis in 1926.

Case 3.—A male, aged 31, was admitted to Glenomond in 1921 suffering from tuberculosis of spine and lupus, and died there in August, 1923. Ten days before he died he coughed up material from which a bovine organism of attenuated virulence for the rabbit was isolated. A daughter, aged 6, had excision of glands of the neck in 1926.

One of the ten cases reported by Griffith and Muir is that of a female, aged 32, who had two sisters and one brother, who died of "acute tuberculosis" several years previously.

DISCUSSION

The measures taken for the control of tuberculosis depend upon a knowledge of the epidemiology of the disease, and in the case of human type infection the mechanism of spread is sufficiently well understood to permit the promulgation of preventive measures, which are—at least theoretically—adequate. The purpose of this paper is to draw attention to a serious gap in our knowledge of the epidemiology of bovine type infections—namely, whether transmission can occur from one human being to another, or whether the condition is self-limiting and the extent of bovine type infection in man is dependent solely on the amount of tuberculosis in cattle.

At present, administrative measures designed to eradicate human tuberculosis of bovine origin are directed towards improvement of milk supply and the quality of dairy herds. The value of such is less apparent if proof of propagation of the disease from human to human is forthcoming. Of possibly greater economic importance is the danger of the introduction of tuberculosis into a clean herd by a person working among cattle while suffering from open pulmonary tuberculosis and coughing up bovine type bacilli. It is a common experience that a person who is delicate and has a "weak chest" is sent to the country and often to a farm for a "change of air." In five out of twenty-six cases of pulmonary tuberculosis due to the bovine bacillus investigated at Glenomond there was close association of the patient with cattle. If such people move about from one farm to another, as, for example, in changing their employment, the possibilities are obvious.

It is realized that the mere occurrence of familial disease due to the bovine bacillus will not prove transmission by humans unless infection from a common source is definitely excluded, and, indeed, it is remarkable that heretofore no instance of this kind has been recorded.

In the absence of proof of transmission to contacts, it is of interest to inquire whether there is any peculiarity of the bovine bacillus or of the disease produced by it which would point to a limitation of spread of the disease by infected human subjects. An outstanding feature of tuberculosis of bovine origin is the high incidence of glandular disease in children in the 0-5 years group, and the disproportionately low incidence of visceral disease in the later age periods. This disparity is not related to the virulence of the bovine bacillus, but suggests that it has a lower invasive power than the human type, so that extension beyond the lymphatic system occurs less readily and so the majority of bovine infections in childhood do not lead to late visceral disease. But when spread does occur beyond the lymphatics the organism shows a high virulence and a tendency to produce multiple lesions and in some cases a marked degree of generalization, similar to that resulting from experimental inoculation in rabbits. This combination of low invasive power and high virulence recalls the cultural characteristics of the organism, and may be in some way related to the latter. Bovine bacilli are dysgonic on all artificial media, and are difficult (as compared with human bacilli) to establish in primary culture, but by subculture they can be induced to grow luxuriantly. Their persistence and tenacity of life when once established in culture is well illustrated in the case of a mixed growth of human and bovine bacilli which, when kept in the incubator for some months, yielded only dysgonic cultures, the eugonic element having apparently died out.²

If it is not accepted that the bovine bacillus has a lower invasive capacity, and has greater difficulty in causing progressive disease in man, is there an alternative explanation of the low incidence of visceral tuberculosis in adults? It has been suggested that mutation of type occurs in the human body, so that an infecting bovine organism after many years in human tissues acquires the characteristics associated with human type bacilli, and becomes manifest as such in chronic pulmonary tuberculosis in adults. Against this it may be pointed out that the type characteristics of tubercle bacilli are remarkably stable, less than 3 per cent. showing divergence in cultural character or virulence from standard types, and no range of transitional strains is found. Further, attenuation does not appear to be related to the age of the patient. For example, a bovine strain isolated at Glenomond from a case of hyperplasia of the large bowel in a patient aged 58 was found to be of standard virulence, and strains isolated from pulmonary cases where the personal history of tuberculosis extended over periods of three, five, and seven years were also of standard virulence. One strain was isolated from sputum on two occasions with an interval of four years between, and no alteration in virulence was found.

Another point worthy of consideration is the number of bacilli observed in the sputum of cases due to the bovine bacillus. In the earlier cases investigated at Glenomond it was noticed that the bacilli were present in very small numbers, but this does not hold good for the more recent cases, where sputum rich in tubercle bacilli has been obtained. In one case they were present in enormous numbers, and this virus was grown from the sputum only after many attempts, although easily isolated by animal inoculation. So far as contact infection depends upon the number of bacilli thrown off in sputum, there seems to be no reason why it should not occur as easily with bovine as with human type cases.

CONCLUSION

There is no proof that spread of bovine type tuberculosis by humans occurs.

There are opportunities for contact infection under conditions similar to those which cause spread of tuberculosis due to human type bacilli.

It is suggested that the bovine bacillus has a lower invasive capacity than the human, and produces progressive disease less readily.

ARTIFICIAL PNEUMOTHORAX

AN AFTER-HISTORY OF 113 CASES

BY

R. R. TRAIL, M.D., F.R.C.P.

PHYSICIAN, ROYAL CHEST HOSPITAL; LATE MEDICAL SUPERINTENDENT, KING EDWARD VII SANATORIUM, MIDHURST

In a recent paper on the effect of fluid complicating artificial pneumothorax the after-history of forty cases was considered in detail. These forty were exactly half the number of sputum-positive cases in which I was able to induce a pneumothorax between 1924 and 1930, and in which for various reasons refills have ceased. All cases have been followed up to November, 1933, so it is now possible to compare results (1) in forty cases that did not develop fluid and forty that did, and (2) in the total eighty cases with "successful" inductions, and thirty-three "control cases" where induction was not successful. At the time when induction was decided on, each case was allocated to a "choice" I, II, or III in accordance with the type and extent of disease, but these subdivisions have not been included in the present summary.

TABLE I.—Cases Successfully Induced: No Fluid. Still Alive

	T.B. +	T.B. - and No Sputum	Totals
Completed treatment ...	4	21	25
Re-expanded ...	1	2	3
Refills stopped for fresh disease in other lung	2	3	5
Totals ...	7	25	33

Thirty-three of the forty cases that did not develop fluid during the treatment are alive, and twenty-six of these are sputum-free or have negative sputum. Four of these had laryngeal tubercle: all four are soundly healed. Under the heading "completed treatment" are given those in whom refills were carried on for at least three years and until such time thereafter as it was considered safe to re-expand the lung. Four of twenty-five in this category are now sputum-positive; two became positive again soon after re-expansion, and in both phrenic-evulsion was performed, while one of them also had sanocrysin, but both have developed signs of disease in the better lung. The other two became positive at intervals of a year and two years after the re-expansion.

"Re-expanded" cases are those where for no apparent reason the lung re-expanded during the treatment by refills. Of three such patients two again became sputum-positive; one refused any surgical intervention, and has now extensive bilateral disease; the other had severe haemoptysis, and Mr. Tudor Edwards performed thoracoplasty with such success that the patient has been symptomless and fit for work for two years.

In five cases refills were stopped because fresh disease appeared in the better lung; two remain sputum-positive;

of the three who have again become negative two had phrenic evulsion and one sanocrysin.

Seven of the forty patients are dead. In six the immediate cause was extension of disease; one of these was treated with bilateral pneumothorax for a year; though the larynx healed the patient went steadily downhill. Only two of these six cases had become sputum-negative at any time during the treatment. The seventh died of lymphadenoma.

Thirty-three cases of "controls" have been followed up over the same period. These are cases which were chosen for pneumothorax on the same criteria as the eighty where induction was successful but where induction was not possible as no free pleural space or only a small pocket was found, or where a pneumothorax could not be maintained beyond a few refills owing to the presence of adhesions too gross and too numerous to justify submitting them at that time for cauterization.

TABLE II

	Alive		Dead	Totals
	T.B. +	T.B. - or No Sputum		
No space or pocket only...	6	4	11	21
Adhesions	—	1	11	12
Totals	6	5	22	33

Table II shows that the prognosis in these "control cases" is grave, and is much more so in those cases with adhesions as against those with no free pleural space, as only one of twelve is still alive as against ten of twenty-one. All were treated or advised on treatment by extensive rest, and forms of ancillary treatment were given full consideration. Only three of the twenty-two dead would consider even the minor operation of phrenic evulsion; of the six alive sputum-positive cases one has had phrenic evulsion and one thoracoplasty, and both are in fair condition.

For purposes of comparison the eighty cases where it was possible to induce pneumothorax have been grouped under the heading "successful," and they have been subdivided into those which did and those which did not develop signs of fluid during the treatment, while the thirty-three "control cases" have been labelled "unsuccessful." Table III summarizes the results; it gives the numbers and percentages alive and dead under each subdivision, and among those alive the numbers and percentages sputum-positive, sputum-negative, and fit for work.

TABLE III

		Alive						Dead		Totals
		T.B. +		T.B. - or No Sputum		Fit for Work				
		No.	Per cent.	No.	Per cent.	No.	Per cent.	No.	Per cent.	
Successful	No fluid ...	7	17.5	25	65.0	27	67.5	7	17.5	40
	Fluid ...	6	15.0	25	62.5	24	60.0	9	22.5	40
Unsuccessful ...		6	18.2	5	15.2	6	18.2	22	66.6	33

From this table the following points emerge:
With a three-year to nine-year after-history,

1. Of eighty "successful" cases, sixty-four (80 per cent.) are alive, and of these fifty-one (63.75 of the total) are now tubercle-negative or have no sputum.

2. Of thirty-three "unsuccessful" cases only eleven (33.3 per cent.) are alive, and of these but five (15.2 per

cent. of the total) are now tubercle-negative or have no sputum.

3. Of eighty "successful" cases, fifty-one (63.75 per cent.) are now fit for work, as against six (18.2 per cent.) of thirty-three "unsuccessful" cases.

4. Of eighty "successful" cases sixteen (20 per cent.) are dead; of thirty-three "unsuccessful" cases twenty-two (66.6 per cent.) are dead.

5. The end-results in "successful" cases, with fluid and without fluid, are practically parallel.

OCULAR TORTICOLLIS: INFERIOR OBLIQUE TENOTOMY AND ITS INDICATIONS

BY

E. TEMPLE SMITH, M.B., F.R.C.S.ED., F.R.A.C.S.,
D.O. OXON

HONORARY OPHTHALMIC SURGEON TO THE ROYAL ALEXANDRA HOSPITAL
FOR CHILDREN AND THE ROYAL NORTH SHORE HOSPITAL, SYDNEY

For many years I have been vaguely aware of a syndrome associated with overaction of the inferior oblique muscle of the eye, but it is only during the last two years that I have given the subject the attention it deserves. Duane of New York published an article in the *Archives of Ophthalmology* in 1916, but since nothing, so far as I am aware, has appeared in British literature on the subject, I feel that some further reference based on personal experience may not be out of place.

It may not be amiss to remind the reader that, when looking straight ahead, elevation of the eyes is effected by the action of the superior rectus muscles. When, however, the eyes are directed sideways—for example, to the left—elevation is accomplished by the co-ordinated action of the left superior rectus and the right inferior oblique. This is another way of saying that, for purposes of elevation, when the eyes are directed to the left, the right inferior oblique and the left superior rectus are complementary muscles. The reason for this will be obvious on looking at the diagrams (Figs. 1 and 2). When either eye is directed outwards its long axis lies virtually parallel with the line of action of the rectus muscles. Elevation (or depression) as it affects this (outward-turned) eye will find the rectus muscle in a position of mechanical advantage. When, however, the right eye, for example, is turned inwards to the left, its rectus muscle forms, in relation to the long axis of the eyeball, a very obtuse angle. The superior rectus is now at a mechanical disadvantage as an elevator. Indeed, such action can only be minimal. The task of elevation of the right eye when turned to the left is now relegated to the right inferior oblique, which, it will be noted, now lies with its line of action parallel with the long axis of the eye.

ALTERNATIVES? OCULAR TORTICOLLIS OR SQUINT

It would appear that weak action (paresis) of a superior rectus is not very uncommon. Whether it is due to a congenital defect or to a birth injury I do not know; I suspect the latter. The mechanism of the co-ordinated movement referred to above is a delicate one, and when it is deranged the following is what I conceive happens. For the movement of the eyes upward and, say, to the left, a certain amount of nerve energy is available. That moiety which would normally act on the left (weak) superior rectus cannot now act with the usual effect, and so overflows to the other component, the complementary right inferior oblique, causing overaction. This hypertrophies, the initial diplopia becomes accentuated, and the overgrown muscle habitually overacts, resulting in the pronounced upshoot of the eye characteristic of the condition when looking laterally upwards.

To avoid inconvenience from the diplopia the child subconsciously seeks relief in one of two ways. If his refraction (hypermetropia, and especially anisometropia) favours it, he develops a convergent squint and suppresses the offending image. This, I believe, is what most frequently occurs. I have found a considerable number of

FIG. 1.—Primary position.

my case notes, both private and hospital, in which, in addition to the description of the squint, I have noted that, on looking up and to one side, the opposite eye "shoots up." I was not at the time fully alive to the importance and significance of the observation, and merely recorded it. The other way in which the discomfort of

FIG. 2.—Eyes looking to left.

diplopia is subconsciously avoided is by tilting the head to one shoulder, the so-called ocular or pseudo-torticollis. This expedient will occur, as I imagine, where the refraction is normal, and where there is no tendency to lack of fusion, and therefore to the ready suppression of one image. The appearance is quite typical. The boy (I have only met with it in boys, which lends force to the suggestion of birth injury, since boys have bigger heads than girls) carries his head on one side, rather like a bird, and it is this peculiarity which attracts the notice of the parents.

REMEDY

Since the inferior oblique is inserted at the back of the lower surface of the eyeball it can only be reached at its origin. This is from a small shallow depression on the orbital floor, just within the inferior orbital margin, close to the opening of the naso-lachrymal canal. A skin incision an inch and a half long is made, commencing at the naso-orbital angle exactly over the inferior orbital margin (Fig. 3). A lachrymal speculum (Müller's) is now inserted, and the incision deepened through fascia and muscle on to the periosteum of the orbital rim, which is felt for with the gloved finger. This is defined in its whole length as far as the naso-orbital angle. Any bleeding points are clamped with forceps, and the deep fascia

lightly incised just within the orbital margin. Some orbital fat may appear, but it may be ignored. A squint-hook is now passed just within the orbit towards the naso-orbital angle, and the muscle will be withdrawn upon it, and will resemble a flat, grey earthworm. It is muscular throughout, and is also hypertrophied. A quarter of an inch is excised and the wound closed with two or three deep sutures. On two occasions I have encountered some difficulty in defining the muscle, but usually no trouble is met with if the deep fascia is carefully incised. The appearance of the muscle on the hook is quite spectacular, owing to its unexpected bulk.

The result in the head-tilting cases is very satisfactory. The head becomes straight, and diplopia is not complained of. I have performed this operation, apart from three head-tilters, on many old squints which had been rectified but in which this factor of an up-shooting eye remained. In future, in such cases I propose to tenotomize the oblique muscle first and see what effect this will have on the convergence, which was probably first induced by this delinquent factor; but this, of course, will depend on the duration of the squint.

CONSTRUCTION OF A VAGINA FROM A LOOP OF SIGMOID

BY

E. ROCK CARLING, F.R.C.S.

SURGEON TO WESTMINSTER HOSPITAL

In February, 1933, a young woman, aged 26, who was contemplating matrimony, sought advice because she had never menstruated. Her figure and general conformation were those of a well-developed young woman; the breasts were full and well formed; the anterior part of the vulva with the clitoris was normal, but there was no vagina. At the vaginal site it was possible, by pressure, to make a very slight dimple. Per rectum no uterine parts could be felt, though the pelvis appeared to be of normal dimensions. The girl stated that she had sexual feeling.

There was a large reducible left inguinal hernia, the contents of which were tender and seemed solid. The hernia was operated upon, and the opportunity was taken to make a thorough examination of the parts. Both ovaries were normal; the tubes with their frimbriated extremities were normal, but each ended in a long, thin, conical body, which appeared to be the rudimentary half of a uterus. In the peritoneal fold behind the bladder each tailed away into nothing. The left tube and uterine remnant entered the hernia, and possibly the ovary also, but this was not verified.

Inquiry elicited a hesitating admission that monthly periods had been recognized, in spite of there being no loss; it is very doubtful if that was really the case.

The operation for formation of a vagina was thus conducted. The whole sigmoid loop, freed on its left aspect, was examined to determine exactly the arrangement of the blood supply. By dividing the vessels so as to leave the springs of successive arcades intact, a length of seven inches of bowel was so isolated as to receive its blood supply from the lowest branch of the inferior mesenteric. Pulsation at the anatomically proximal—but henceforth the distal—end of the isolated loop was full and strong. Both ends were closed by inversion—the anatomically distal end with great care and thoroughness. The divided parts of the large bowel were then united end to end. An incision was now made in the skin, at the posterior part of the vulval site, and a passage enlarged upwards between the bladder and rectum. As soon as it was large enough a full-size tubular speculum was passed up to its full length.

FIG. 3.—a-b, Line of incision.

Returning to the abdomen, it was found a little difficult to locate the upper end of the speculum, so as to make the safest possible aperture for the isolated loop of gut; but when well placed, the peritoneum over it was incised and the open end of the speculum cut down upon.

A pair of sponge holders was passed up from below, and a ligature on the closed end of the freed sigmoid loop seized and pulled down to the perineum. The peritoneum and such subjacent parts as could be gathered, together with the lower ends of the rudimentary uterine halves, were attached to and round the upper closed end of the new vagina. The lower end was now opened and the mucosa and muscular wall sutured to the skin margin.

At first there was some tendency of the new tube to diminish in diameter, but an obturator of stent, and later one of vulcanite, was provided, so that the lumen might be kept patent. After a few months an interesting observation was made: about a couple of inches within the orifice a band of circular muscular contraction, about one-half to three-quarters of an inch in extent, was encountered by the examining finger. The first stimulus to the mucosa excited a very strong contraction, which gripped the finger, but if gentle pressure were maintained the muscle relaxed completely, and the whole of the rest of the passage could be reached. Eventually the new vagina admitted a full-sized tubular speculum.

At first there was a considerable discharge of mucus, but with simple douching that was controlled, and generally has been very much less, though it has not entirely stopped. Moreover, on two or three occasions there has been a slight loss of blood, which appeared to come from a little ulcer in the mucosa high up in the passage. The mucosa itself is slowly losing its distinctly intestinal appearance, so that, with the speculum in place, it might pass for a normal vaginal lining.

Marriage, which was postponed for nine months, has been followed by sexual intercourse, believed to be normal. The patient experiences normal sensations, and states that she is able to relax and contract the sphincter-like muscular tract, if not quite at will, certainly with conscious effort. It is an interesting question whether this very definite sphincter-like section of the sigmoid loop represents the sphincter responsible for Hirschsprung's megacolon and allied conditions.

In this case the mesentery of the small intestine was very short, and to have carried a double loop successfully to the perineum would have been a difficult task; indeed, it appeared impossible without putting such tension on the vessels as would have made the life of the loop extremely precarious.

Upon a review of all the circumstances it seems to be wiser to use colon rather than small gut; at any rate, this case indicates that, as an alternative, the colon is available.

The prospective husband was informed of the circumstances, the findings, and the implications. The psychological and other aspects of the whole undertaking were carefully considered.

This is not the first use of sigmoid for the construction of the vagina. At least five cases are recorded—those of Albrecht, (three), Boldt and Rüge¹—and probably there are others.² A short bibliography is attached to Mr. Norman Hodgson's report of a successful case, using small intestine, in the *British Medical Journal* of May 13th, 1933 (p. 822).

For the success of this case I am indebted to the skilful and patient co-operation of Miss Burton, the ward sister.

LEAKING CEREBRAL ANEURYSM

BY

G. D. KERSLEY, M.D., M.R.C.P.

MEDICAL REGISTRAR, ROYAL UNITED HOSPITAL, BATH

As cases of leaking cerebral aneurysm diagnosed *intra vitam* are unfortunately still rare, the case mentioned below seems worthy of record. It is of additional interest, moreover, in that the leak occurred during an eclamptic fit, which somewhat complicated the diagnosis.

CASE REPORT

A multipara, aged 38, was sent into hospital as a case of ante-partum haemorrhage. The history revealed nothing of note except that six months previously she had experienced a sudden intense occipital headache, which had gradually subsided. There was no history suggesting renal involvement. On admission the patient did not appear very ill, but there was marked albuminuria and a blood pressure of 215/140; there was no oedema. There were no labour pains, but the cervix was three fingers dilated; the placenta could not be

A = Ruptured aneurysm. B = Second aneurysm, unruptured.

felt. The following night the patient suddenly fainted, labour pains began, and there was a large discharge of blood from the uterus. The membranes were ruptured, and shortly afterwards a stillborn child was delivered. The mother was very collapsed, with a pulse rate of 130 and a blood pressure of 140. Two hours later she had a fit, lasting six minutes, with opisthotonos and clonic movements of the limbs. Under treatment for eclampsia with morphine and chloral she improved a little, but remained somewhat cyanosed. Till the fourth day there was little change, the patient remaining drowsy. The temperature rose to 101°, the breasts became very tender, and at the same time the patient became more lethargic. The blood pressure had now risen to 180.

On the sixth day after delivery the patient developed a right hemiplegia. The diagnosis at this stage appeared to lie between that of a leaking cerebral aneurysm or of an embolic cerebral abscess. A uraemic hemiplegia was also considered, as was a syphilitic thrombosis, but this was thought to be unlikely. After due consideration it was decided that the most probable diagnosis was leaking aneurysm, and this was confirmed by lumbar puncture, when the cerebro-spinal fluid was found to be intimately mixed with blood, with a coloured supernatant fluid after centrifugalization. The only other findings in the fluid of note were a urea content of 40 mg. per cent. and a negative Wassermann reaction. The patient gradually became more comatose, and died on the tenth day. On post-mortem examination a small ruptured

aneurysm was found at the origin of the left middle cerebral artery, and another aneurysm, about 3 mm. in diameter, was situated close by on the posterior communicating artery.

On reviewing the case it seems likely that six months previously the patient had a slight leak from a congenital aneurysm. In the latter months of pregnancy she became toxæmic, and this resulted in an accidental hæmorrhage and, finally, in an eclamptic fit, which caused the aneurysm to start leaking again, with a fatal result.

COMMENTARY

Cerebral aneurysms, both symptomless and as a cause of cerebral hæmorrhage, certainly, occur more frequently than has in the past been recognized. They are found in about 1 per cent. of all necropsies where the arteries of the brain are examined, but Busse records the presence of small aneurysmal dilatations on the anterior communicating artery in as many as 10 per cent. of all post-mortem specimens. Their origin, in the majority of cases, is due to a congenital weakness of the pars media, usually at the junction of two vessels, and they have been found as early as the second year of life. Embolic phenomena are, however, responsible for a certain number of aneurysms, as also, occasionally, are arteriosclerosis and syphilis.

The infrequency of *intra vitam* diagnosis of cerebral aneurysm is not surprising when it is realized that until hæmorrhage occurs, as eventually it nearly always does, there are no symptoms unless calcification or clotting has taken place, for then, and only then, do pressure symptoms arise. These, of course, vary according to the site of the aneurysm, and can only be diagnosed from those due to neoplasm by the observation of calcification in the wall of the sac on x-ray examination, or, better, by means of an arterio-radiogram. When bleeding occurs it may be sudden, with a rapidly fatal result, or there may be a series of leaks, with subsequent clotting at intervals of months or even years, and death may not occur until as long as twenty years after the first hæmorrhage. It is in this type of case, where there are repeated small hæmorrhages, that a diagnosis is frequently possible. The leak may be subdural, with the formation of a hæmatoma, sometimes causing symptoms similar to those of encephalitis lethargica; it may be into the subarachnoid cavity, causing meningism, or into the brain substance, with transient hemiplegia, aphasia, or an attack simulating severe migraine. The attack may be accompanied by albuminuria or glycosuria.

Of great value in the diagnosis of aneurysm leaking into the subarachnoid cavity, as of subarachnoid hæmorrhage from any cause, is lumbar puncture, when the fluid will be found to be evenly mixed with blood, which will have caused staining of the fluid after the cells have been removed by centrifuging. Red cells may be found in the cerebro-spinal fluid for about three days after a hæmorrhage, but the fluid will be coloured for a period of three or four weeks.

The ultimate results of treatment are not promising, as hæmorrhage, even if it ceases for a time, nearly always recurs. Collier advises repeated lumbar puncture so long as the cerebro-spinal fluid pressure is above normal, and Schmidt suggests pressure on the common carotid artery followed later by ligature of the internal carotid. This seems rather a heroic procedure, but it is certainly justified by the poor results of more palliative treatment.

Clinical Memoranda

EXTREME HYPERGLYCAEMIA IN DIABETIC COMA

From time to time various figures of extreme hyperglycaemia in diabetic coma have been published from different countries, almost vying with each other, as sportsmen do, for the record. None has to date exceeded the blood sugar concentration of 2.06 per cent. observed in 1930 in one of my cases. This sounds more like a urinary than a blood sugar analysis, but the figure was confirmed by multiple analyses of the blood filtrate by McLean's method.

The case was one of profound and prolonged diabetic coma in an elderly woman, who was almost pulseless and so weak that air-hunger was replaced by rapid shallow breathing. Two hours before this high blood sugar figure 40 units of insulin had been given; another 40 units afterwards, with abundant saline, reduced the blood sugar to 1.568 per cent., so that the initial figure may have been even higher before any treatment. The patient died in spite of all efforts.

R. D. LAWRENCE, M.D., F.R.C.P.,

Diabetic Clinic, King's College Hospital.

A CASE OF HEART-BLOCK

The following notes on a somewhat unusual case would appear to be worth recording.

The patient was a medical man, seen in consultation with Dr. R. O. Eades and Dr. Bessie Armour. At the time he was taken ill he was carrying on a large general practice. He was very active, and was a golfer. In his time he had been an athlete and also a climber and a shot. Some years ago, when in the sixties, I had advised him to give up swimming, because of transient attacks of precordial pain. During this period he had been subject to pains of the nature of angina, and on one or two occasions had had fainting attacks. He had, however, never been laid up, and had led a regular, normal, hard-working life.

On the night of May 27th, 1932, he was awakened with violent pain in his chest and intense dyspnoea. He was greatly distressed, and became very restless. His pulse was very weak at the wrist, and the rate was below 40. His doctor was called in, and he was given morphine, with a certain measure of relief. The next day, when I saw him, the pulse rate was 36 and the rate at the apex was the same. The heart sounds were distant, and an apical systolic murmur was present. His blood pressure was 120/80 mm. Hg, and the respirations were rather rapid—36. He was cyanosed and suffering a great deal of respiratory distress. He was constantly clutching at his chest, which appeared to relieve him.

It seemed clear that he was suffering from heart-block. The suddenness of the onset and the urgency of the symptoms suggested a coronary occlusion of some kind, but the extreme slowing of the pulse indicated that a complete heart-block was present. Morphine was given at intervals; strychnine at his request, and oxygen and CO₂ from a Yandell-Henderson apparatus, were administered. Two electrocardiograms were taken the same afternoon and are here reproduced (Figs. 1 and 2). They show a four-to-one heart-block with idioventricular beats. Fig. 1 shows a normal QRS in Lead 1, but suggests a left bundle-branch block in Lead 3. Fig. 2 shows the left bundle-branch block well marked in Lead 1, with a very evident negative T-wave. There is complete dissociation of the auricles and the ventricles.

On the third day the patient had severe hæmoptysis, accompanied by pain on the left side of the chest. At the same time his temperature, which had been normal, ran up to 101.6°. Friction subsequently developed over the area

of pain, with a patch of dullness and numerous rales. There had been an infarction of the left lower lobe. Gradually the haemorrhage ceased. His distress to some extent was mitigated while he was on oxygen and CO_2 , but the precordial pain never entirely went, nor did the dyspnoea leave him. The pulse rate ranged from 28 to 32, his temperature remaining subnormal.

On the night of June 11th he had another attack of agonizing pain, when it was thought he most certainly must succumb. This lasted for some hours, but he was not given morphine, lest it should administer the *coup de grâce*. The next morning he was still very ill, but his pulse rate began to rise and reached 60. The following day he expressed himself as quite a new man; something appeared to have

FIG. 1.

FIG. 2.

FIG. 3.

"moved" in his chest. He breathed perfectly comfortably; he did not wish for any oxygen. When I saw him he had a pulse rate of 72, and the rate at the apex was the same. Another electrocardiogram was taken at this time (Fig. 3). In it will be noted: a regular rhythm; normal relations of auricular and ventricular complexes; and that the appearances of damage to the right bundle have completely vanished, but a left axis deviation persists.

Whether anything actually happened in the patient's coronary circulation must be a matter of conjecture. It would seem as if the blocked vessels had almost suddenly become patent, with the result that normal conduction of impulses from auricle to ventricle re-established itself. From this time onwards recovery was uneventful. It was difficult to keep him even in bed until the end of six weeks. He gradually got about, but wisely decided to retire from practice, and is now able to garden and play nine holes of golf.

Reviews

GASTRO-DUODENAL HAEMORRHAGE

For their monograph on large haemorrhages of gastro-duodenal origin¹ Professor TIXIER and Dr. CLAVEL have made a study of seventy-four cases of haemorrhage observed in the clinic of Professor Tixier, and seventy-nine haemorrhages among 400 cases of gastric diseases in the clinic of his colleague Professor Savy, together with 200 cases from the literature. The authors are aware of the considerable divergence of opinion within the profession as to the proper method of dealing with these cases, and in their view this hesitancy about methods is due to an inadequate recognition of the causes of gastro-duodenal haemorrhage and the inferences to be drawn from a study of the mechanism by which the haemorrhage is brought about.

The surgical treatment of gastric haemorrhage has a "bad press" because operations are done too late and they often deal inadequately with the cause. In making a case for earlier surgical rather than expectant treatment in these patients the authors divide them into four groups, each with a distinctive mechanism causing the haemorrhage. In the commonest—the haemorrhage from the erosion of a vessel in a callous ulcer, usually on the lesser curvature of the stomach or in the upper duodenum—the mechanism is that of a secondary haemorrhage from a large vessel, such as occurs in an infected wound elsewhere in the body; the artery wall is eroded and damaged, and spontaneous haemostasis is exceptional. Though the first haemorrhage rarely is fatal, it almost certainly recurs. Medical treatment is therefore unlikely to be satisfactory, and direct procedures are necessary—early operation, ligation of the vessel, followed by excision of the ulcer or partial gastrectomy. In a second group haemorrhage occurs in pyloric or duodenal stasis. In these cases it is not the ulcer or cancer which bleeds, but the mucous membrane, which has become infected as the result of retention. The haemorrhage may be slight, but in many cases is enough to endanger life. Treatment should be devised to relieve the stasis—gastro-enterostomy in pyloric stenosis, duodeno-jejunostomy in duodenal stenosis. In stenosis caused by bands and adhesions externally, simple division of these is enough. Operation should not be pushed, but time given to prepare the stomach by lavage. Gastrectomy is unnecessary. In another group haemorrhage occurs from local or diffuse gastritis; it is usually in the nature of a capillary oozing, unless an associated ulcer has eroded a vessel. The treatment is essentially medical, dieting, haemostatics, and transfusion of blood if necessary; intravenous saline solution is to be avoided. Where ulcer is suspected—for example, in men over 40, with a history of indigestion, or where bleeding continues—exploration is indicated. Should an ulcer be found it should be resected if in the stomach or gastro-enterostomy be done if in the duodenum. When no ulcer can be found it is unsafe to do simple gastro-enterostomy, though sometimes successful; it is better to incise the stomach and search further, even to perform a considerable gastrectomy or jejunostomy. The indications for surgical intervention are a reduction of the red cells to $2\frac{1}{2}$ millions per c.mm. or haemoglobin to 40 per cent. of normal.

A fourth large and varied group of haemorrhages arises from causes outside the stomach, whether in neighboring abdominal viscera, cirrhosis and lithiasis of the liver, splenomegaly, appendicitis, or from general states of infection, intoxications (uraemia), anaemia, arteriosclerosis,

¹ *Les Grandes Hémorragies Gastro-duodénales*. Par L. Tixier et C. Clavel. Paris: Masson et Cie. 1933. (Pp. 240; 56 figures. 45 fr.)

and hypertension. These haemorrhages of extragastric origin are by no means rare; they are at least as frequent as haemorrhages arising from ulcer. Their treatment requires the active collaboration of physician and surgeon. It is dangerous to treat all cases only medically; it is even more serious to deal surgically with all cases. Certain other varieties of gastric haemorrhage are described, such as those following operations on the stomach, immediately from faulty technique with relaxation of the suture line or following infection, from gastrojejunal ulceration, associated with perforation; or the obscure form where no cause can be found (gastrostaxis, Hale-White). All these varieties are discussed, and the indications for treatment, while a good bibliography follows each section. Finally, there is a section on methods of operative technique, and a number of plates illustrating the operations advocated. The book is well worthy of perusal.

THE INTERVERTEBRAL DISKS

A well-illustrated monograph on the Anatomy, Physiology, Pathology, and Treatment of the Intervertebral Disk,² by G. MAURIC, who has had special experience at the well-known hospital at Berck-sur-Mer, and has carried out investigations on the anatomy of the disk, is the first work on this subject to appear in France, and follows the Special Report publication of the Medical Research Council by Dr. O. A. Beadle in 1931, to which references and deference are duly made. The author has also made a critical survey of foreign literature, especially of Schmorl's observations on ten thousand spinal columns between 1925 and 1931 at Dresden, where Beadle also worked. The references to Mauric's monograph amount to nearly four hundred. In the section on anatomy it is pointed out that the intervertebral disk may undergo an early senile change after 30 years of age as an isolated lesion, no other part of the body being affected, and without any obvious disability. Four-fifths of the text are devoted to the pathological and clinical aspects. Attention is drawn to hernial protrusions of the intervertebral disks into the spinal canal, which are commoner in women than in men, are more frequent in the lower dorsal and lumbar region, more often lateral than median, and project from the posterior surface of the disk from the gelatinous nucleus, undergo cartilaginous transformation and ossification, and may press on the spinal cord. The subject of compression of the spinal cord by these fibro-cartilaginous nodules when of considerable size, which has been comparatively recently recognized, is dealt with at length and illustrated by twenty-six collected cases; laminectomy, however, has not always given entirely satisfactory results. Other morbid changes in the intervertebral disk are described, but the most detailed account is that just mentioned.

-HISTORY OF EPIDEMICS

In his *Short History of the Epidemic Infectious Diseases*³ Dr. E. W. GOODALL has carried out with success the difficult task of condensing the main points of importance in a subject which forty years ago was examined voluminously by that tragic figure Charles Creighton and before that by August Hirsch. Since then this task has certainly not become any easier—for example, the carrier problem has necessitated an account in which it is pointed out that Sudhoff has unearthed the statement, in the *Treatise on Fevers* of Bartholomew of Santa Sophia in

the fifteenth century, to the effect that a person may be infected with, but not be ill of, plague and yet infect others. Celsus, in the first century of the Christian era, wrote: "Rarely, yet occasionally, a new disease appears," and in the accounts of subsequent writers on diseases the adjectives "new" and "unknown" abound; but with regard to infectious diseases Dr. Goodall would not admit that this ever occurs, though observers may think so, as in the case of Brill's disease in 1898 and encephalitis epidemica in 1918, which were rechristened with new names. In the chapter on notable epidemics the nature of the much-discussed plague of Athens, during the second year of the Peloponnesian War, 430 B.C., is considered, and while regarded as more probably typhus or small-pox, may just conceivably have been "an unknown disease which has long disappeared"; the unusual epidemic character of erysipelas, experienced in North America seventy to a hundred years ago in some respects recalls the plague of Athens. It is remarkable that there is not any mention of infectivity in the Hippocratic corpus, especially as the contemporary account of the plague of Athens given by Thucydides supplies distinct evidence of it. The first medical writer to suggest that the spread of disease is due to infection was Aretaeus in the second century A.D., when Galen also pointed out the risk of associating with those suffering from the plague, scabies, and ophthalmia. An interesting point brought out is that both inoculation and vaccination against small-pox were first in vogue among the poorer classes, methods of the first being known as "sowing" and "buying" the small-pox.

A FREUDIAN VIEW OF MENTAL DEFECT

Although a vast amount has been written on the psycho-analytical investigation of the normal and the mentally disordered, no book has hitherto been published dealing with this subject in relation to the mentally defective. This omission has now been remedied, and in *The Nature and Treatment of Amentia*,⁴ by Dr. L. PIERCE CLARK, we have a volume dealing with the subject of mental deficiency entirely from the standpoint of the Freudian psycho-analyst. To the ordinary reader with no knowledge of Freudism, perhaps even more so to the one who has made a study of mental defect, the book may at first be unintelligible; it may possibly even strike him as unmitigated nonsense. If, however, he will read the author's preface and his introductory outline of the main tenets of the Freudian doctrine, and if he will try to look at the question impartially, he may then succeed in appreciating the author's point of view, and he may, in some measure, be able to understand the purport of the detailed case studies which comprise the greater part of the book.

The author does not ignore the possibility that mental defect may be based upon inadequate neuronic development, or even that this, in its turn, may be due to germ variation or to cerebral injury; he also agrees that "the ego defect lies within such capacities as perception, memory, ideation, judgement, and reasoning"; but he believes that such lesions may "cripple mental development, not directly, but through its burden of handicap upon the ego and the libidinal processes necessary for mental growth and functioning." In case this may not be clear it will be well to give a quotation from the author's summary of the problem of idiocy, which will, no doubt, make the matter quite intelligible. He says:

"We have attempted to show how much and how far we may detach libido from the primary narcissism and place it

¹ *Le Disque, Intervertebral. Physiologie, Pathologie, Indications Therapeutiques.* Par G. Mauric. Préface du Pasteur Valléry-Radot. Paris: Masson et Cie. 1933. (Pp. xii + 195; 46 figures. 35 fr.)

² *A Short History of the Epidemic Infectious Diseases.* By E. W. Goodall, O.B.E., M.D. London: John Bale, Sons and Danielsson, Ltd. 1934. (Pp. 113. 3s. 6d. net.)

³ *The Nature and Treatment of Amentia.* By Dr. L. Pierce Clark, assisted by the staff of the Psycho-Analytic Sanatorium at Rye, N.Y. London: Baillière, Tindall and Cox. 1933. (Pp. xvi + 305. 12s. 6d.)

to the service of the oral function, thus starting these infants on the road towards a real objective cathexis. Even when the primary narcissism is to some degree broken down in establishing an oral identification, it is extremely difficult to gain displacements upon persons and things other than those belonging specifically to the mother pattern. It all becomes a test of our ability to engender a good counter-transference of the narcissistic type. Only then will these little charges, caught up in the maelstrom of a more or less enduring state, find it worth while to be enticed away from their self-engrossment and accept satisfactions to the secondary narcissism. . . . Yet we shall have to look to the higher levels of mental arrest if we are to hope for demonstrable therapeutic results."

Unfortunately, these results do not appear to be forthcoming, for towards the end of the book Dr. Clark says: "If it is at all possible to analyse the feeble-minded, they certainly need much more time than the average in which to carry out such a process of absorption." It would therefore appear that the doubts which have been expressed in some quarters as to the possibility of benefit resulting from psycho-analysis in cases of mental disorder are even more justified in the case of the mentally defective. This being so, the person who is not already a fervid disciple of Freud will probably consider it a waste of time to read this book. On the other hand, the thorough-going Freudian may conceivably think it a useful addition to his knowledge.

PRACTICE OF SURGERY

It is almost exactly twenty years since *The Practice of Surgery*,⁵ by RUSSELL HOWARD, first saw the light of day—the preface to the first edition bears the date January, 1914. Now a fourth edition, in which Mr. ALAN PERRY has collaborated with the author, has recently been published. In this, particular attention is paid to methods of diagnosis and treatment, and the central idea of maintaining the work as a textbook for students preparing for examination, and a groundwork for more specialized study, has been adhered to. Methods of treatment of controversial value and highly specialized operative procedures and laboratory tests have been omitted or very briefly indicated, so that the mind of the student should not be burdened with matters which may soon be of no practical value. Mr. Russell Howard has been known to generations of London Hospital men as a teacher of the very first class, at whose feet disciples have ever been known to crowd in almost inconvenient numbers. This experience, coupled with that as an examiner at the Royal College of Surgeons, must have given him an exceptional knowledge of the needs of the student, and how best they can be met. For *The Practice of Surgery* he drew upon this rich store of experience, and the publication of a fourth edition may be taken as evidence that it has met and continues to meet with the full approval of those whose requirements it is designed to serve.

The book is well illustrated by photographs, line drawings, and many excellent radiograms. If we might offer a little gentle criticism it would be that in future editions more care might be exercised in the literal reading of the proofs: we should then be spared such a sentence as appears on page 505: "With these splints, as in all cases of fractured tibia and fibula, and should be taken that the foot is not placed vertically on the foot-piece, etc." A similar revision of the index is also necessary, as, for instance, a reference to poliomyelitis is given for page 294, whereas in the text it appears on page 298. These are slight blemishes on an admirable textbook.

⁵ *The Practice of Surgery*. By Russell Howard, C.B.E., M.S., F.R.C.S., and Alan Perry, M.S., F.R.C.S. Fourth edition. London: Edward Arnold and Co. 1933. (Pp. 1,338; 8 coloured plates and 584 figures in text. 30s. net.)

PHOSPHORUS METABOLISM

The scope of the monograph entitled "Phosphorus,"⁶ by Professor M. LABBÉ and Dr. M. FABRYKANT, is indicated in its subtitle, "Chemical Technique, Physiology, Pathology, and Therapeutics." The authors give a full account of the functions of phosphates in the body, the normal metabolism of these substances, and the chief pathological derangements which may be encountered in relation to it. They have taken a wide view of the subject, for they include an interesting summary of existing knowledge regarding the part played by phosphate compounds in muscular contraction, whilst another chapter is devoted to phosphatases. The absorption and excretion of phosphorus and the physiology of blood phosphorus are also fully dealt with. The discussion of the last-mentioned subject includes an account of certain important experiments carried out by one of the authors.

The second half of the book is concerned with the pathology of phosphorus metabolism—rickets and tetany, and the influence on these conditions of vitamin D and parathormone. It is pleasant to note that the authors have given an adequate account of the remarkable work of Schabod, who between 1908 and 1912 demonstrated quantitatively that administration of cod-liver oil caused rickety children to retain phosphorus. Unfortunately, the pathology of both rickets and tetany is still obscure, because of the difficulty in determining the relative importance of derangements in the metabolism of calcium and of phosphorus. Furthermore, it is still uncertain whether rickets is due to a failure to absorb these minerals from the gut or to a failure to utilize them after absorption. The authors incline to the latter view, but give a full record of the existing evidence. Finally, phosphorus metabolism is discussed in relation to a large number of pathological conditions—osteoporosis, anaemia, diabetes, liver disease, nephrosis, etc.

This brief review indicates the general scope of the work. The two chief qualities we look for in such a volume are that it should provide a guide to all the important evidence available, and that it should present a readable summary of the chief conclusions that can be drawn from this evidence. The monograph fully satisfies both these requirements. It gives a full and impartial account of work published in all languages, and the conclusions are clear.

Notes on Books

John Bale, Sons and Danielsson have published new editions of *Efficiency in First Aid*,⁷ by Dr. N. CORBET FLETCHER, and of *Accidents and Emergencies*,⁸ by A. T. GOODING. The former has now reached its third edition, totalling 10,000 copies, and thus indicating its popularity with senior students of first aid. The subject is dealt with critically as well as comprehensively, and ambulance instructors will find it useful for that far from uncommon person who finds the official handbooks too compressed and unimaginative. Both diagnosis and treatment are discussed in detail and systematically, and hints are given which should help to make training and examination more vivid and searching. Mr. Gooding's booklet, now in its second edition, is described as "an ideal memorizer and a quick reference"; it has been compiled from the textbooks of the St. John Ambulance Brigade and the British Red Cross Society. It should prove of service to those preparing for examinations and others wishing to revise and check their knowledge. The injuries are listed in alphabetical order.

⁶ *Le Phosphore*. Par M. Labbé et M. Fabrykant. Paris: Masson et Cie. 1933. (Pp. 393. 55 fr.)

⁷ *Efficiency in First Aid*. By N. Corbet Fletcher, M.B. Third edition. London: J. Bale, Sons and Danielsson, Ltd. 1934. (Pp. 196. 1s. net.)

⁸ *Accidents and Emergencies*. By A. T. Gooding. Second edition. London: J. Bale, Sons and Danielsson, Ltd. 1934. (Pp. 62. 1s. net.)

Organic and Biochemistry,⁹ by Professor R. H. A. PLIMMER, is a well-known textbook, which was first published in 1910, and has now reached its fifth edition. During its career it has twice changed its title, for the first edition was called *Practical Physiological Chemistry*, the next three editions *Practical Organic and Biochemistry*, while the present edition has been amplified to cover both the theoretical and the practical aspects of the subject. In spite of these changes in title the general form of the book has been maintained fairly constant. The book provides a very clear introduction to organic chemistry, and particular attention is devoted to compounds of special biological interest. Great care has been taken to bring the present edition up to date, and accounts are given of all important recent advances, such, for instance, as the chemistry of carotene and vitamin A, of ergosterol and calciferol, of the oestrogens, and of ascorbic acid. About three-quarters of the volume deals with organic chemistry, whilst the last quarter is devoted to the chemistry of the digestive processes, blood, urine, and foodstuffs. The book therefore covers a wide range of subjects, and the latter portion of necessity presents a somewhat condensed account of the material with which it deals. Adequate accounts are given, however, of all the most important methods used in clinical medicine, and the author has saved space by describing methods actually in use and

by omitting accounts of methods that have become of historical interest only. The present edition fully maintains the past reputation of the textbook for accuracy and for careful selection of material.

We would again recommend *The Annual Charities Register and Digest*¹⁰ to all who seek authentic information concerning the special institutions, hospitals, hostels, and educational establishments which provide relief for the distressed in sickness and misfortune. In the forty-first edition, which is now available, a new section has been included which lists the relief stations, children's receiving homes, training centres, etc., of the Public Assistance Committee of the London County Council. The volume may be obtained from the Charity Organization Society, Denison House, Vauxhall Bridge Road, London, S.W.

The tenth edition of PARK and WILLIAMS's well-known textbook *Pathogenic Microorganisms*¹¹ has been enlarged and thoroughly revised, especially in the sections dealing with active immunization against diphtheria and scarlet fever, yellow fever, poliomyelitis, bacteriophage, and undulant fever. The authors are to be congratulated on the care which they take to keep this useful reference book up to date, and so well indexed and lavishly illustrated.

⁹ *The Annual Charities Register and Digest, 1934*, Forty-first edition. London: Longmans, Green and Co., Ltd. (Pp. 523; 5s. 6d. net.)

¹¹ *Pathogenic Microorganisms*. By W. H. Park, M.D., and A. W. Williams, M.D. Tenth edition. London: Baillière, Tindall and Cox, 1933. (Pp. 868; 215 figures, 11 plates. 35s.)

Preparations and Appliances

A SIMPLE METHOD OF APPLYING A PLASTER JACKET TO CASES OF FRACTURED SPINES

Mr. R. JACKSON, M.B., C.M. (consulting surgeon, St. Helens Hospital), writes:

In a mining area such as this, where the roof of the mines is not very high, and where "falls" are liable to occur, a fracture of the spine is of quite common occurrence. It may be a simple crushed fracture of the body of a vertebra, or a fracture of the spinous process and laminae, or a combination of both. Such fractures are commonly caused either by a fall of roof on the shoulders of a miner when in a sitting or stooping position, or by a blow on the shoulders or at the seat of the fracture when illegally riding on a "tub" to

The patient is then rolled over on to a loose pole canvas stretcher, face downwards, on which he is lifted to the hammock, his head, arms, and shoulders resting on the head of the bedstead. The canvas stretcher is withdrawn, and the plaster bandages are applied round the patient's body and the hammock. The patient is very comfortable in this position and remains so until the plaster is set, when he is released by cutting across the towelling above and below the jacket, the intermediate portion of the towelling remaining as part of the jacket. The "dinner-pad" is then removed. When the laminae or spine of the vertebrae are fractured,

FIG. 1.—The patient in position on hammock ready for encasing in plaster.

FIG. 2.—The patient encased in plaster jacket waiting for plaster to set.

or from his work, from a low bar or projecting portion of the roof. A convenient and easy way of applying a plaster jacket to these cases, and a method I have used for many years with success, is as follows.

A hammock is made by stretching a piece of roller-towelling on a suitable frame, which can readily be made by removing the foot-piece from a hospital bedstead and putting a head-piece with smooth top-rail in its place. The towelling is then stretched across this frame, and, by tightening or slackening the towelling, the necessary hollowing can be given to the patient's back. The patient is then prepared by being fitted with two singlets: the outer one becomes part of the jacket, while the inner one can be changed as required during the wearing of the jacket. A "dinner-pad," about 8 in. by 6 in. and $\frac{1}{2}$ in. thick, to which tapes are attached for withdrawal, is placed under the singlets over the abdomen.

and the bodies are not crushed, the patient may be placed face upwards.

This is a method which is easily carried out anywhere, and I have used it for jackets in tuberculous spines, etc., when suitable. The jacket is much lighter and stronger if a long strip, about one inch wide, of roughly perforated tin (such as is used by tinmiths for making bread-graters), is incorporated in the plaster as a reinforcement on each side of the spine. When the jacket is dry it may be varnished with a solution of celluloid—for example, acetone collodion.

During the three years ending in March last I had seventeen cases of fractured spine—one, who had fifteen other bones broken, died at the end of twelve months from cystitis, eleven have been certified as fit for suitable work, the remaining five are able to walk, four of them being over 55 years of age, and one having a large diaphragmatic hernia.

THE HOSPITAL OF THE FUTURE

BY

DUNCAN C. L. FITZWILLIAMS, M.D., CH.M.,
F.R.C.S.

There is a saying that the old order changeth, giving place to new; but change is not always manifest, and in some departments of our civilization it seems, for a time, imperceptible, and then characterized by a period of great activity. One sees this in the building of new hospitals. I am not here referring to the style of architecture, though that has changed quite suddenly, but to the internal arrangements and the ideas which pervade them.

Originally, hospitals were charitable institutions founded, for the most part, by religious orders out of pity for their fellow men, for the relief of suffering humanity—for those who rattled in the streets, heggars who could no longer beg, men broken in the wars, those in the last stages of disease, and for few else. Shelter and sustenance were of primary importance, and the medical side took second place. Once admitted to the institution the inmates could remain there indefinitely. Gradually through the ages the almshouse features were lost and the medical side grew until it became the all-important feature of the institution as we see it to-day.

Lister's discoveries revolutionized hospital organization, and his influence spread far beyond surgical confines. It introduced cleanliness everywhere, and banished the "smell of new-mown hay" which pervaded the institutions owing to the number of pyæmic cases in the wards. The tiled or terrazzo floors, the rounded corners, the new paint, and the general air of freshness associated with these institutions to-day are all due to Lister's genius. Since those great changes consequent upon his discoveries, we have been experiencing one of those pauses already hinted at. Public health authorities have influenced the water supply, sanitary arrangements, lighting, and other social services, but there has been no great revision of ideas and no marked changes. If we were to ask any of the charitably inclined members of the boards of our institutions what reforms they would recommend, ninety-nine out of a hundred would be hard put to it to think of any. In other words, we are quite content with things as they are. But to those who understand the evolution of the hospital another long stride forward is due, and it is time that the finger of criticism, or even of scorn, should be pointed at some of our customs. I shall cite two which are anachronisms embodying some of the most barbaric features of the Middle Ages.

DEATH IN PUBLIC

It is customary in our hospitals to allow a patient to die in the public ward. Nothing could be more crude or unnecessary, for surely dying is as private an affair as birth to the patient and his immediate relatives. Imagine the scene in a large ward at night with the darkened lights casting mysterious shadows on the walls, screens round one of the beds, and nurses gliding to and fro as noiselessly as possible, but with evident hurry and anxiety. The deathly silence preserved by the other patients in the ward is broken only too audibly by the strange and horrible noises emitted by the semi-conscious patient. Then there is the hurried sending for the house-surgeon, the consultation with the sister outside the screens, in view of everyone except the patient and his friends, the gestures of helplessness and inability to do more which everyone can understand. The oxygen is hurried in by the porter and pushed behind the screen. Silence is broken by a loud hiss which startles all but the dying as the over-anxious nurse turns on the tap a little too vigorously, or the silence is broken in a still more alarming manner by a loud pop as the buckled tube is blown from the end of the cylinder. Every noise is multiplied a thousandfold by the tension of the nerves of the listeners. The sounds from behind the screens become fainter and fainter till at last the silence is broken only by the sobs of the relatives. Later there are the almost silent flittings of

the nurse behind the screens as she performs the necessary last rites, and lastly the arrival of the porter with the dismal covered trolley on which the body is removed. In circumstances such as these little sleep can come to the other patients, as they lie awake with straining, horror-struck eyes which gaze timidly about to see what the others are doing and how they are taking it. Imagine the psychological effect of all this upon a nervous individual fighting for his own life and health in a near-by bed—nothing could be more cruel, more unnecessary, or worse, medically, than to subject him to such an ordeal.

OPERATION CASES IN THE WARDS

There is another feature of our hospitals to which we are equally callous—namely, the admission of a young and inexperienced man, about 18 years of age, into a surgical ward preparatory to an operation, say, for hernia. He enters a strange building where, after a wait of variable length, he is shown up into a ward. He is not ill, but he is told to undress and get into bed. Like the new boy at school, he knows no one, and understands little of his surroundings. He notices that there is a curious arrangement like a small house under the blankets of the next bed, which at the moment is empty. A nurse may come from time to time to examine it, and he sees that the house-like contrivance is full of electric lights over which the bedclothes are draped, and he wonders what all this is for. Presently steps are heard coming along the corridor and the door is bumped open by the end of a trolley pushed by a porter. The nurse whisks away the small house, and arranges the bedclothes as the trolley is brought alongside the bed and a groaning patient is transferred from the trolley to the bed next to him. A towel is arranged under the head of the patient, and an ominous-looking basin placed near at hand. Then the ordeal begins. The new patient is horrified at the sights and sounds that follow—the groaning, the incoherent talk, the vomiting, and all the disgusting features of a patient, his actions shorn of human semblance, slowly regaining consciousness after an operation. Timidly he may inquire what it is all about, and a nurse may inform him shortly that it is only a case of hernia which has been operated on that afternoon. Only a case of hernia! He is a hernia case too! But this may not be all; the surgeon of the ward may be operating that day, and three or four similar cases may be placed in the same ward that afternoon—perhaps a case operated upon for tonsils and adenoids, in which the sight of quantities of blood-stained expectoration are added to the other horrors. Is the new patient, in this environment, likely to pass a pleasant night? And what must be his thoughts of his own approaching ordeal? I have instanced a case of hernia, but the deleterious effect would be multiplied a thousandfold, and might assume serious features, if the case was one of exophthalmic goitre awaiting operation.

When I hear some of the leaders of our profession speak proudly of the march of science and the progress of medicine, and lay stress on the growing importance of psychology, I sometimes wonder if their tongues are in their cheeks, for they must know the two scenes I have endeavoured to depict are everyday occurrences in the wards of their own hospitals.

THE REMEDY—"DEATH ROOM" AND "RECOVERY
WARD"

Now let me deal with the remedies for these two anachronisms which, now they are pointed out, will, I hope, soon become customs of the past.

In the first place, each hospital should provide one or two small wards into which a person about to die can be removed. This should be insisted upon both for the convenience of friends and relatives and even more so in the interests of the other patients. During the war I organized three hospitals, and in each a ward for the dying was provided. I never saw wards for the dying provided in any military hospital except my own, but I have heard that something approaching them was arranged at Salonika. It might be argued that the act of being transferred to the ward for the dying might have

a detrimental effect on the patient. A moving picture of such an occurrence is portrayed in the novel *All Quiet on the Western Front*. To me, with experience in this matter, the scene was totally false; the patient was never removed until he had lost sense of his surroundings. Incidentally, it showed that the need for such wards was recognized even in the German hospitals, where we should hardly look for sentimentalism. In Archangel, during the 'flu epidemic, we had a ward of sixteen beds set apart for such cases, and for a time it was almost continually filled. I only knew of one mistake being made, where the man actually lived and returned to the general ward. Being a bit of a "wag," he never failed to make reference to his little excursion when I made my rounds.

To remedy the second state of affairs recovery wards should be provided, where patients recovering from the effects of the anaesthetic can be nursed till the disagreeable effects have passed off. Most of them could be returned to the general wards in twenty-four hours, and the worst cases would only remain in the recovery ward for two, or at the most three, days. When the new Freemasons' Hospital was being built I strongly recommended the provision of these recovery wards of six beds for each sex—a low partition between each bed, with, perhaps, a curtain at the foot to make supervision easy. To the patient in his semi-conscious condition, with the senses dulled by morphine, his surroundings would not matter, and he would not be made more miserable by the presence of neighbours in like state. I could not, however, get all the surgeons to agree upon the subject, and some to whom the idea was new said they much preferred their patients to be nursed in the wards in which they would subsequently lie. The point of view of the other patients did not appeal to them. Nevertheless, the suggestion was considered by the building committee, who have wisely set aside small wards for this purpose and, although they are not quite what was originally suggested, their value is already appreciated.

OTHER REFORMS

There are other, but perhaps less important, reforms needed in our hospitals. To my mind it is pathetic to see patients sitting in low chairs eating meals from high bedside tables, or, still more inappropriately, from their beds. A dining room should be provided for those who are up and about, or, failing this, there should be a central table in the ward at which they could have their meals. Some of the features of a hydropathic establishment are sadly needed in our hospitals, for what is useful in one establishment would be equally useful in the other. The next suggestion, which obviously goes with the last, is the provision of a sitting room, reading room, or library, where papers, periodicals, and books are provided. He who wishes to cavil at these suggestions may say that the pressure on our large hospitals is such that we do not have convalescent cases. Such, however, is not the case, for at least 10 per cent. of the patients could get up if there was room for them. In our present hospitals the provision of space for these changes is almost impossible. I am, however, speaking of the hospital of the future, where provision could and should be made for these improvements.

Another necessary feature sadly wanting in many hospitals is the provision of a good convalescent home. A hospital without a good convalescent home is like a man with one leg. By a convalescent home I do not mean a place where a patient is sent to and lost sight of, but somewhere where he can convalesce after his operation. After the seventh or, at the most, the tenth day, a case operated on for hernia occupies a bed and needs little attention. He could quite well be looked after in a convalescent home. Most of the so-called convalescent homes to which patients are now sent are merely boarding establishments, with no resident medical staff. There is usually a proviso that the patient must be able to get up and about and must not require any dressings; no medical treatment can be undertaken, and there is no touch with the establishment from which the patient came, except through the almoner who

arranges the admission. It is to these establishments that the term "convalescent home" is now applied.

A definite feature of every hospital should be an efficient follow-up system. It is only needed for a very few diseases, but they are of vast importance, and include all slowly fatal ones—chiefly blood and lymphatic diseases—and all forms of malignant disease. It would, perhaps, be best for the follow-up system to be under the management of the public health authorities, so as to ensure uniformity, efficiency, and the collection and good use of the statistics produced. The notes of the patient would follow him from institution to institution if necessary. The follow-up department would keep in touch with the patients, who would report themselves at certain times. There are most excellent follow-up departments in connexion with the cancer institutes on the Continent, and we have copied them at our cancer centres, though it seems more difficult here to make the patient see the importance of this department. In Sweden free railway tickets are issued to patients who wish to report at the centres. The follow-up system also keeps the hospital in touch with the general practitioner who supervises the patient at his home.

FUTURE DEVELOPMENTS

There are many reasons why the ideal hospital will not be built in this country for some time to come, for we have become wedded to two opposing systems—(1) the voluntary hospital, which prides itself on its efficiency and advertises its unbusiness-like behaviour by exaggerating its debts in the hopes that it will thereby appeal more strongly to the generosity of the public; and (2) the municipal hospital, recently brought up to date by the Board of Health, under the skilful guidance of Sir Frederick Menzies. From now on the latter type of hospital is going to be an efficient and serious rival of the voluntary hospital for public favour. This is already recognized by the voluntary hospital; considerable jealousy has been evinced, and the medical profession has even been induced, half-heartedly, to take sides. Neither side is likely to scrap its methods, but the bringing up to date of the municipal hospital is going to have a far-reaching effect on the voluntary hospital, and whether the voluntary hospital will survive remains to be seen. If in the future the Government were to take over the whole hospital system of this country they would have central purchasing boards for food, dressings, drugs, and equipment, and a great saving would result. Such central boards could be introduced now with the same advantages if the hospitals could be induced to combine. At the moment many of the voluntary hospitals cannot provide the equipment specified by the staff as they cannot find the money, and some of the reforms mentioned cannot be introduced for the same reason. It is perfectly possible to visualize a fusion of the two systems at some future time, simply because many voluntary hospitals may not be able to compete with the Government establishment, where everything would be provided. Thus the municipal hospital may become the more favoured by the public.

Where does the opposition to fusion come from at the present moment? Partly from the leaders of the medical profession, many of whom are conservative in outlook and do not take readily to new ideas. What is the attitude of the younger men? Have they shown any repugnance to entering the service of the municipal hospital and being paid for the services they render to the State? Not at all; they clamour for the posts. The day of the honorary staff is passing. The pressure of life and taxation is rendering it impossible for a medical man to give his services for nothing in the way he used to do. He should be the last to regret the change. Far more serious opposition will come from the Government, who will not want the added expense or the responsibility. If charitable people will provide the money, it is unlikely that the Government will wish to shoulder the burden, though the Government has built and staffed nearly all the hospitals in our Crown Colonies. They are, incidentally, excellent institutions.

Alongside the general hospitals, voluntary and municipal, and perhaps because of them, there will appear another sort of hospital for the better-class patient. These private hospitals ought to cater for the middle class and contain private rooms and small wards for two, four, six, or eight patients according to their means, wards for the dying, recovery wards, dining rooms, and reading rooms. Few people really object to small wards. The upper middle classes, as represented by officers in His Majesty's services, are provided with wards in Millbank Hospital if they are under field rank, and a very well run private hospital for officers does the same thing for nearly all ranks. This also is the experience of anyone who has worked in large nursing homes where small wards are provided—they have been the greatest success in the Freemasons' Hospital.

Doubtless there will be fashionable institutions run by titled ladies with a gift for nursing or management, and in my experience these places are run with remarkable efficiency—their vogue would not endure long if they were inefficient. Smart society and the plutocracy would insist upon admission. There would be no difficulty in making prices to correspond in every way.

SILICOSIS: RIVAL THEORIES

The discussion on silicosis, held under the auspices of the Institution of Mining and Metallurgy, of the first part of which some account appeared in the *Journal* of February 10th (p. 254), was completed on February 15th. It was noteworthy for a brisk exchange between Professor J. S. Haldane, who holds the view that the cause of silicosis is a dust with a high percentage of quartz, and Mr. W. R. Jones, D.Sc., of the Royal School of Mines, who maintains that it is the minute acicular fibres of sericite.

At the resumed meeting Professor S. Lyle Cummins sent a communication stating that the information which Dr. Jones had collected about the distribution of sericite in rocks and its close correspondence with the distribution of silicosis had brought to the problem of pneumoconiosis an entirely new concept, which fitted in better with the observed facts than that based on the theory that what was called silicosis was due entirely to free silica. Those who had studied the problem in the South Wales coalfield, said Professor Cummins, had always been conscious of the underlying uncertainty as to how some of the miners had managed to breathe in sufficient free silica to explain the condition found. The possibility that it was combined silica which was causing the damage was now supported by very convincing evidence, and he for one was deeply impressed by Dr. Jones's findings. He suggested that they might be finally established by the production of experimental silicosis in animals by means of sericite.

On the other hand, Dr. S. W. Fisher, medical inspector of mines, said that he still adhered to the view that silicosis was a pathological condition of the lungs due to the inhalation of silicon dioxide in a chemically uncombined state. To his mind the evidence regarding the danger of the inhalation of dust containing a high percentage of free silica was overwhelming; whether sericite played a part in this remained to be proved. Dr. J. S. Owens also contested some of Dr. Jones's conclusions, and said that he felt that Dr. Jones had not advanced any acceptable proof of the absence of large numbers of very fine quartz particles from the air of mines where silicosis was common—that is, particles well below one micron in diameter. He considered that the presence of sericite fibres and the absence of silica from the lung tissues which Dr. Jones had examined might be due to the greater solubility of the silica, and did not necessarily mean that sericite was the cause of the disease present.

MEASURES FOR PREVENTION

A good deal of the discussion was occupied with measures for the prevention of silicosis. Dr. Jones had put forward a twofold proposal: that the less mobile

workers should be provided with a light cover for the mouth and face and a supply of fresh air from compressed-air pipes, and that the more mobile workers should be provided with a supply of compressed air carried on their backs; but Mr. F. H. Wynne, deputy chief inspector of mines, considered that very few coal miners in this country could be included in the first category, and as regards the self-contained supply from a cylinder, he was very doubtful as to its practicability. The better way was to attack the dust either at its source—the borehole, for example—or, in so far as that was not possible, by means of respirators. He said that the method of extracting dust before it reached the atmosphere, by means of a so-called dust-trap, and depositing it in a filter, was now largely employed in South Wales. Professor B. W. Holman, however, suggested that the provision of a separate supply of air for each man was not so impracticable as it sounded, and according to some calculations he gave, it worked out at one penny per hour per man.

Professor Haldane said that he looked for a remedy in the stone-dusting of a dangerous mine with a dust which would sufficiently dilute the free silica. Other speakers suggested a reinvestigation of ventilation in mines, the possibility of blanketing the fine dust after it had settled by a layer of innocuous dust, or the addition of a chemical to the water spray to assist in wetting the sericite (supposing that to be the culprit), sericite being not easily wetted by water alone. Professor J. G. Lawn, as one intimately concerned with silicosis-prevention in South Africa, spoke of the disappointing results there. Nearly twenty years ago the Miners' Phthisis Prevention Committee in South Africa succeeded in laying 97 or 98 per cent. of the dust, but no very striking diminution of silicosis incidence had followed, although in addition to laying the dust other hygienic measures had been taken, and it had been ensured that only healthy workers were recruited. It was mentioned by another speaker that the incidence of new cases in South Africa was now slightly under 2 per cent. per annum, as compared with about 2.6 per cent. some ten years ago.

Dr. Jones, in replying to the discussion, warmly defended his hypothesis. He quoted the figures recently given in Parliament showing that while the South Wales coalfield employed only 18 per cent. of the coal miners in this country, it accounted for 89 per cent. of the cases of silicosis. Dr. Jones contended that the bulk of these cases came from a localized anthracite area, where sandstones occurred just above or just below the coal seams, and these and the sandy shales had been shown to contain myriads of minute fibres and scales of sericite. In the Scottish coalfield, on the other hand, where there were few cases of silicosis, the sandstones contained very few such fibres.

The fourth International Congress on Rheumatism will be held at Moscow, May 3rd to 6th, 1934. The following subjects will form the basis for discussion: (1) the problem of the clinical aspects of rheumatic fever; (2) indications for the balneological treatment of rheumatic patients; and (3) social and occupational aspects. Among other speakers Dr. G. P. Cawadias will contribute to a discussion on metabolism in rheumatism; Dr. B. Schlesinger, on clinical aspects of rheumatic fever in children; and Dr. R. Fortescue Fox, on balneological treatment. There are two ways of travelling in order to attend the congress. (1) To take a three-week tour (giving twelve days in Russia), leaving London on April 21st for Leningrad, by boat, and then on to Moscow; the inclusive cost of this (boat and railway travel and hotels) is £23 third class, £38 second class. (2) Those who have less time can travel overland via Harwich, The Hook, Berlin, Warsaw, Negoroje, to Moscow; the return ticket from London to Moscow is £46 first class, £36 second class with sleepers, £28 10s. second class without sleepers, £19 third class. Accommodation in the U.S.S.R., by the day (covering all expenditure), costs £3 first class, £1 15s. second class, £1 5s. third class. Further information can be obtained from the secretary, S.C.R., 1, Montague Street, W.C.1.

PHYSICO-CHEMICAL BASIS OF ANTIGEN-ANTIBODY REACTION

During the last decade the work of chemists and physicists who have been engaged upon the fundamental problems of immunity has contributed much towards their solution by bringing them into relation with the theories of modern chemistry and physics. A recent account,¹ written by Dr. J. R. Marrack and issued by the Medical Research Council, provides an excellent summary of the chemical and physical studies which have served to elucidate certain specific immunological reactions in terms of the fundamental sciences. It may be well at the outset to recall some of the more important researches which have advanced our knowledge of the nature of the antigen-antibody reaction, and to note in particular those which have illuminated the subject of immunological specificity and its relation to chemical composition and structure.

The changes in the immunological specificity of proteins which result from modifying their chemical and physical structure were investigated at the beginning of the present century by Obermeyer and Pick, who showed that the nitration, diazotization, or halogenation of proteins brings about the disappearance of the original specificity and gives rise to a quite different specificity which is characteristic for the nitro-, diazo-, or halogen-protein that is formed. Landsteiner and his co-workers extended these observations, and demonstrated that the specificity of a protein may also be altered by reactions such as esterification, acetylation, or methylation, which involve the salt-forming groups of the protein molecule as well as those of the hydrogen atoms in its aromatic nuclei. Proteins that were altered by such chemical treatment were found to behave as foreign proteins when injected into animals of the species from which they were derived; the corresponding immune sera exhibited a specificity which depended on the simple chemical grouping that now formed part of the synthetic antigenic complex. An antigen prepared by introducing the same chemical grouping into a different protein from that used for the immunizing antigen reacted in a completely specific manner with the immune serum.

Although these methods of investigation have yielded results of the greatest value, and have definitely established the paramount part played by the dominant chemical groupings in the antigenic constitution of artificially altered proteins, Landsteiner realized that

more exact knowledge could only be obtained by determining the serological properties of simple chemical substances of known structure that had been rendered antigenic by linking them with protein. Examination of the serological properties of the antigens derived from the dextro-, laevo-, and meso- forms of tartaric acid² after combination with protein indicated that the steric configuration, as well as the chemical nature of the dominant chemical grouping, is a material factor in the specificity of these artificial antigens. These results are of especial interest and significance because the chemical constitution of tartaric acid is closely allied to that of the sugar acids which have been isolated from certain specific bacterial polysaccharides. Further evidence concerning the nature of chemical structure in its relation to antigenic specificity has been procured by coupling simple carbohydrates of definite stereochemical configuration with protein of known antigenic properties and analysing the new antigenic complexes so obtained. Thus it has been observed³ that when the two simple carbohydrates— β -methyl-glucoside and β -methyl-galactoside—which differ only in the spatial configuration of a single carbon atom, are combined separately with the same protein, the antigens so formed possess distinct specific characters.

It has long been known that filtrates from bacterial cultures frequently contain a soluble product which gives specific precipitation with the homologous immune serum. Dochez and Avery isolated type-specific substances from actively growing pneumococcus cultures which were identified later as complex polysaccharides derived from the bacterial capsule. This work forms the basis of current theory concerning the antigenic structure of the bacterial cell. The researches into the variable morphological characters of bacteria and their colonies that were initiated by Arkwright and extended by many other workers have proved that variations of this kind are intimately related to antigenic structure and to virulence. In some instances—for example, the pneumococcal types—the antigenic variation can be explained in terms of chemical composition. The virulent forms of the three classical types of the pneumococcus possess a capsule which is composed of a polysaccharide that is absent from the corresponding non-virulent forms of the organism. It is now certain that the capsular substance, which is different for each type, is responsible for the strictly type-specific serological reactions of the pneumococcal strains, and in some way not yet fully understood for their virulence in an infected animal host.

When the specific polysaccharide substances were first isolated from the "smooth" or virulent forms of bacteria, they were regarded as partial antigens, because they failed to induce antibody formation but gave specific precipitation when mixed with an anti-bacterial immune serum prepared against the corresponding whole organism. In theory there is no known reason why polysaccharides, which are colloidal in form

¹ *The Chemistry of Antigens and Antibodies*. By J. R. Marrack. Medical Research Council Special Report No. 194. H.M. Stationery Office, 1934. (2s. 6d. net.)

² Landsteiner and van der Schoot. *Ann. Exp. Med.*, 1929, 1, 47.

³ Goebel and Avery. *IBI*, 1929, 1, 521, 531.

and of large molecular weight, should not be antigenic ; nevertheless, until quite recently, no complex carbohydrate of bacterial origin had been discovered which possessed the property of forming antibodies. It seemed reasonable to believe that the bacterial polysaccharides that had been isolated and found to be devoid of antigenic power had in some way become degraded during the process of isolation. With this idea in mind Avery and Goebel^{*} re-examined the chemical and immunological properties of the capsular substance of pneumococcus Type I. They have ascertained that this polysaccharide is extremely sensitive to the action of alkali, and that if the process of isolation from the bacterial cell is carried out with the careful avoidance of alkaline treatment an acetyl-polysaccharide is obtained which is antigenic in mice and, in its highly purified form, accounts for all the serological type-specific properties of the whole organism.

Dr. Marraek's monograph deals in a very lucid manner with such investigations as have been reviewed above, and it explains in terms of modern chemical theory many facts which the immunologist has brought to light by his own special methods, but has found difficult of exact interpretation in purely biological terms.

THE PROBLEM OF MEDICAL CARE

The Medical Secretary of the British Medical Association from time to time sends out from the head office a circular letter, on matters of current professional interest, to the presidents, chairmen, and honorary secretaries of home Divisions and Branches, representatives, and members of Council, and central committees. In his "Occasional letter" for September, 1933, Dr. Anderson dealt with the problem of medical care, and asked each Division to study this from the particular point of view of its own locality. The appeal was not in vain, and in his February letter he is able to record that many Divisions have now got to grips with that part of the problem which appears to be of major importance in their areas. But—such is human nature—there still remain areas in which members have so far had no opportunity of voicing their opinions about matters that cannot fail to affect their professional relationships with the community. Many Divisions have given serious attention to the advisability of establishing a local public medical service under the control of the profession, and since the beginning of this session many requests have come from Divisions for a speaker from headquarters to explain in detail the working of such a service. Some Divisions have already established a public medical service, and in others schemes are in process of formation.

Other Divisions are tackling the proposal for the "open choice" method of attendance upon the public assistance patient (known in former days as the Poor Law patient), and it is good to know that in this

endeavour Divisions are receiving the active co-operation of the medical officers of health concerned. Perhaps the most complete scheme now in operation is in Wiltshire, where the local authority, acting on the advice of the county medical officer of health, has agreed to give free choice of doctor to the public assistance patient in those localities where the district medical officer does not still retain a vested interest. The capitation fee paid to the doctor is per patient attended, and works out at 25s. a year inclusive of medicine but exclusive of mileage, which is paid in addition at the rate of 6d. a mile both ways beyond the usual two-mile radius. Any complaints that may make themselves heard, or difficulties that may arise, are to be considered by a medical advisory committee set up by the Wiltshire Branch of the British Medical Association in conjunction with the medical officer of health, so that the interests of the patient, the Public Assistance Committee, and the practitioner himself may be conserved ; but no serious interference with the smooth working of the scheme is anticipated. An account of the scheme appeared in the *Supplement* of February 17th. What has been done in Wiltshire can be done elsewhere, given good will on all sides.

The need for consideration of the hospital problem has impressed itself on other areas, and meetings have been held to give the members of these Divisions an opportunity of listening to an exposition by someone who is familiar with the British Medical Association's Hospital Policy in its general application. Adaptation of the Policy in detail to suit local circumstances must necessarily wait upon understanding and appreciation of the broad outlines. Personal contact between centre and periphery is of the utmost value in elucidating the many linked problems that make up the problem of medical care. London, with a dozen undergraduate medical schools, with a vast array of voluntary hospitals both general and special, and with seventy-four municipal hospitals managed by the L.C.C., forms an area of peculiar difficulty when a common professional policy is on the anvil. For this reason we welcome the announcement at page 390 of a meeting of the medical staffs of teaching hospitals called by the Metropolitan Counties Branch for March 22nd to discuss the problem of London's hospital development.

FOOD STANDARDS AND LABELS

A memorandum recently presented to the Departmental Committee on the Composition and Description of Foods by the People's League of Health affirms that in not a few instances statements made in advertisements and on labels relative to the composition and nutritive values of foods are unjustified and misleading, and that the public consequently is deceived and prejudiced. Illustrations in support of this claim are quoted from various sources. Meat extracts, for example, are often presented as "body-building food," "a steer in a tea-cup," and so on, when it is known

^{*} Avery and Goebel: *Journ. Exp. Med.*, 1933, lviii, 731.

that while of value as stimulants such preparations are of little or no value in the direction which the labels announce. Other so-called "potted" meats often contain an almost negligible content of meat, and the bold name on the label is sometimes qualified in very small print by the phrase "sold as a mixture." "Custard" and "egg" powders, often coloured to convey a suggestion of "richness," may be innocent of either of the substances named on the label; baking powder similarly treated offers itself quite unjustifiably as "egg substitute"; "lemon cheese and lemon curd" may decorate a package with contents so prosaic as sugar, tartaric acid, glucose, starch, margarine, gum, and artificial flavouring agents, instead, as the purchaser fondly believes, of lemon juice, egg, sugar, and butter; and "lemon squash," announced as possessing "all the virtues of fresh lemons," may depend for justification of its alleged virtues entirely on a minute amount of lemon flavouring. Among dairy products "cream" is used in various food preparations, including ice-cream, even though the percentage of milk fat present is but a minimum quantity; milk, butter, cheese, margarine, may be artificially coloured in order to suggest high nutritive value; and the proportion of water and of milk fat in various types of cheeses is quite without legal standard or definition. The memorandum pays particular attention to wholemeal flour and bread, and insists that in each instance there should be present a minimum value of 80 per cent. of the whole wheat berry. The employment of any bleaching agent applied to flour is condemned, and the practice is recognized to be widely prevalent. Claims made for various preparations as "rich in vitamins" are often quite without justification, and will doubtless continue to be so until the law demands on the label a quantitative statement which can be tested by reliable methods of assay.

These and similar facts, the League's memorandum urges, demand new legislative and administrative developments in order to protect the public health and the private purse. It is allowed that in some directions the proprietors of certain food preparations have, on their own initiative, adopted standards of quality and purity, but these standards have not the sanction of the law and cannot be enforced in a court of law; and thus the unscrupulous trader benefits at the expense of his more conscientious rivals. What is needed is that the Minister of Health should obtain statutory powers for the regulation of standards, composition, labelling and advertisement, addition of colouring matters, and presence of injurious substances in all materials offered for human food; and the establishment of a standing committee to watch developments in the science of nutrition and in the technology of food manufacture so that such developments could be promptly applied in the public interest. In support of the League's memorandum Professor J. C. Drimmond, University College, and Dr. W. M. Willoughby, medical officer of health for the City of London, gave evidence before the Departmental Committee.

GLYCOGEN DISEASE

A famous surgeon, with a great interest in freaks and monsters, animal or human, once justified his hobby by saying, in effect, that when Nature exaggerated or made a mistake it was often possible to learn a great deal about some normal process of development or physiology. So, too, the accurate study of a rare disorder of metabolism may throw some light upon the normal chemistry of the body, and although the number of cases of excessive glycogen infiltration of the liver now on record is still small, investigation of what is usually termed "von Gierke's disease" has revealed many points of interest. In the current number of the *Archives of Disease in Childhood* Dr. S. van Creveld of Amsterdam describes his experience with two children suffering from this complaint. Briefly, the clinical picture is that of a child with infantilism, a very large smooth liver, adiposity, and a combination of low blood sugar and ketosis in the fasting state. The injection of adrenaline fails to produce the usual distinct rise in blood sugar, and the ketosis is increased. After the ingestion of glucose the blood sugar curve is abnormal, with a prolonged period of increase above the fasting level. The glycogen content of the blood is increased, and there is an increase in the blood cholesterol. Dr. van Creveld has been particularly concerned with the chemistry of glycogen in this condition. He finds that the blood and urine possess a normal degree of diastatic activity, and at first sight it is difficult to understand why glycogen accumulates in the liver. After injection of insulin there was no "initial hyperglycaemia" in the two cases studied, and this is interpreted as indicating that though there was abundant glycogen in the liver it could only be mobilized with difficulty. Investigation of the increased quantities of glycogen in the blood, for which a new method has been devised, showed that the glycogen present in the blood of the two patients could only be split with difficulty after incubation at body temperature, although glycogen added to the serum of these two children was normally split. The results of adding normal serum to the blood of the two patients were not conclusive. The next steps have been to study the nature of the glycogen present in these abnormal conditions. The possibility of some unusual combination with protein, as suggested by earlier workers, has not so far been confirmed. Certain facts suggest that other internal secretions than insulin may in part control the glycogen metabolism of the body. It is significant in this connexion that the first case reported by von Gierke had atrophy of the suprarenals, while other cases described have shown abnormal pigmentation and growth of hair. The possibility of a persistence of what may be termed a foetal type of glycogen metabolism has also to be considered, especially in view of the congenital nature of the affection. Dr. van Creveld discusses also the occurrence of glycogen infiltration in other organs of the body, such as that found by him in the so-called idiopathic hypertrophy of the heart and by other observers even in the pyloric muscle in congenital pyloric stenosis. The differential diagnosis from other affections of the liver in childhood is easy once the peculiar features of the disturbance of carbohydrate metabolism are realized.

February, 1934. Published by the British Medical Association. Yearly subscription 36 shillings, 25/-; single numbers, 4s. 6d.

Many problems of the disease still remain unsolved, and, in view of its rarity, it seems justifiable to suggest that other workers should also attempt what Dr. van Creveld has done in the way of an extremely careful and detailed study.

GINGIVITIS OF PREGNANCY

In spite of the fact that pregnancy gingivitis was described more than fifty years ago very little is known concerning its incidence, aetiology, or treatment. This fact is made abundantly clear by reference to the standard English textbooks on obstetrics, which either omit mention of the condition or dismiss it in a few lines, the views expressed being widely dissimilar. The preliminary report of a clinical, histological, and experimental study of pregnancy gingivitis by Ziskin, Blackberg, and Stout¹ is therefore of considerable interest. Clinically, these authors recognize four forms of this gingivitis, which may or may not be different stages of one condition. The first is characterized by bleeding of the gums. In the second form only the free gum margin is involved, more commonly in the region of the anterior teeth, and takes on the colour and appearance of a raspberry, being designated "raspberry red gums." The third form is a generalized hypertrophy of the tissue and is usually confined to one section of the mouth. Lastly comes the so-called "pregnancy tumour," which resembles an epulis, differing from it by the fact that it may either disappear entirely or diminish considerably in size after parturition. Histologically the significant change in the gums was found to be hyperplasia of the epithelium. The clinical study was based on the examination of the mouths of 416 pregnant women, but it is not clearly stated whether this was a consecutive series of women attending an ante-natal clinic, or a selected group referred for dental treatment. Of the 416 patients 37.9 per cent. had some form of pregnancy gingivitis, of which 70 per cent. belonged to the hypertrophic group. The fact that 400, or 96.1 per cent. of all these patients, had some form of irritation in the mouth suggests that the gingivitis might have been secondary to the source of irritation. The authors are inclined to the view that the gingivitis is associated with "hormone change," such as occurs during pregnancy and menstruation and at puberty, and sought to obtain confirmation for their views by experimental studies on rats and monkeys. The results obtained with rats were inconclusive, but in one monkey a series of injections of prolactin was associated with a definite hyperplasia of the epithelium without inflammatory changes in the submucosa. There would appear to be general agreement that gingivitis commonly occurs after the fourth month of pregnancy and tends to disappear after delivery, although the condition may first make its appearance with the onset of lactation. The point which has not been satisfactorily determined is whether gingivitis may arise in perfectly healthy mouths during pregnancy or whether the pregnancy causes a marked exacerbation of a pre-existing condition, and it is to be hoped that in subsequent investigations the use of x rays will not be

omitted. In a more recent paper C. B. Reed² suggests that pregnancy gingivitis is due to deficiency of vitamins C and D in the diet. Other work would indicate that this view is more plausible than that advanced by Ziskin, Blackberg, and Stout, and if found correct would support the view that the health of the expectant mother and her unborn child is largely dependent on the food she eats, both before and during pregnancy.

THE THIRD MOLAR

For the first time in history the Arris and Gale Lecture was delivered before the Royal College of Surgeons, on February 21st, by a dental surgeon. Mr. Bowdler Henry took as his subject the third molar tooth, and showed himself duly invested with the mantle of his predecessors by surveying his subject from anthropological, embryological, paediatric, dental, and surgical aspects. He had collected material illustrating the troubles of the wisdom tooth in many races and more than one species, and he laid emphasis on the great variety and often mysterious character of the symptoms produced by failure of this tooth to erupt properly. John Hunter showed, and many later workers have confirmed, that the dental arch in front of the first molar does not grow appreciably after birth. The large permanent teeth of the adult dentition in front of the first molar must therefore arrange themselves in a space which has been provided for them many years before, and the eruption of the second and third molars must depend on adequate growth of the parts behind the first molar. Mr. Henry concluded, after examining a great many radiograms of the jaws of young children and adolescents, that impaction and imperfect eruption is due to the maintenance of the tooth in its developmental position by the premature arrest of skeletal development. He suggested that one cause is rickets; he is investigating other possible causes. Describing the operative technique for impacted wisdoms which he has developed on the basis of those of G. B. Winter and Boyd H. Gardner, he insisted that a radiographic examination is necessary, and that the operation should be regarded as one of some severity. Failures, some of which had ended fatally, have been due to over-estimation by the operator of his ability to treat the operation as a simple extraction, or his under-estimation of the resistance of the tooth or the general resistance of the patient. The forceful measures adopted by some surgeons often, he said, injure the inferior dental nerve and sometimes even fracture the jaw. Mr. Bowdler Henry's method is to cleave off the crown of the tooth and then divide the roots with a mallet and chisel, removing each part separately. He advocates the prevention of the trouble by removing the lower wisdom teeth between 8 and 10 years of age in all cases in which radiographic examination shows that they will probably become impacted. The third molars, of which the crowns are at this age just forming, lie close to the surface of the ascending ramus and may be enucleated easily and rapidly and with less discomfort than the ordinary extraction of the second molar at 12 or 13.

THE USE OF THE HOUSING ACTS

Medical officers of health and their assistants are constantly wrestling with the problem of defective and insanitary housing, which adds to their work and for which they can often find no solution. An appeal to the owner almost certainly calls out a negative reaction, varying from polite regret to uncivil obstructiveness. To study the Housing Acts, with all their long intricacy, is more than most busy public medical officers can manage, and Dr. James Fenton did his colleagues a great service in a paper read before the Royal Sanitary Institute on February 15th, describing the procedure under these Acts by which owners of defective houses can be made to repair them. Soon after the introduction of the Housing and Town Planning Act, 1919, the Royal Borough of Kensington, advised by the many experienced lawyers on its council, drew up a number of rules of procedure under the Act which have been found safe and effective. Under Section 28 a local authority may serve a notice on the owner of any house suitable for occupation by the working classes who does not keep it reasonably fit for human habitation, requiring him within twenty-one days or more to make it so. If the notice is not complied with and the owner does not declare his intention of closing the house, the local authority can do the work and send him the bill; if he does not pay they can recover their costs with interest in a magistrate's court, and the amount becomes a first charge on the premises. The local authority can declare their expenses to be payable by instalments. One of the council's rules is that in no case shall an order be made for payment by instalments, because if an owner defaults an authority can only sue for the single instalment not paid. Profiting by the experience of local authorities against whom magistrates had decided that twenty-one days was not a reasonable time for notice, and that direct labour was unreasonably expensive, the council established further rules that fifty-six days' notice—a time sufficient to build a house—is to be allowed for the execution of works in every case; and that if at any time they undertook work in default of an owner they would invite tenders from half a dozen builders and accept the lowest, so that he could not say that he could have had the work done more cheaply. Another rule provides that the council shall serve a schedule of repairs in each case and keep copies, so that if tenders have to be invited nothing shall be asked for that the owner has not been required to do. The Housing Act, 1930, by its Sections 17, 18, and 22, much improves the position. When a sanitary inspector is dealing with a house where the owner has been carrying out indifferent or patchy work, he gives a warning that unless the owner improves his methods the house will be referred to the housing inspector. Owners have discovered that if this takes place the house will have to be repaired from top to bottom in a workmanlike manner and made thoroughly habitable, or the council will step in and do it. This warning has in fact been more effective than procedure under the Public Health (London) Act. In the last five years 794 notices have been served and 725 have been satisfactorily complied with. The council has carried out repairs in default of the owners in fourteen cases. Every appeal to the Minister and the County Court has

been decided in favour of the council. When the owner can pay the council's charges an order is obtained for their payment as a civil debt; when he cannot, the town clerk applies to be appointed the receiver, and the property is managed by the council until enough rent has been collected to defray the amount due. Over the whole period during which the council has put this type of legislation into force it has only lost £2, a sum due for interest which it waived when the owner paid the whole of a capital charge of £280 after losing an appeal. These results do not, of course, include the tremendous moral effect they have had on owners who have voluntarily commenced repair work on being served with notices that their houses are to be surveyed. The general state of repair of the houses occupied by the working classes in North Kensington is much higher than at any time in the last thirty years. Dr. Fenton's watertight system should prove an implement of the greatest value to other local authorities.

TYPHUS FEVER IN 1932-3

The epidemiological report of the Health Section of the League of Nations for November-December, 1933, contains, as in the previous year,¹ a valuable survey of the incidence and fatality of typhus fever throughout the world. In Europe, apart from the Iberian Peninsula and the Irish Free State, where a few sporadic cases occurred, typhus was practically confined to the eastern part of the continent, including the Balkans. The chief focus, as in the previous year, was Soviet Russia, where there was a pronounced increase at the end of the winter of 1931-2, and a decline in 1933. There was a slight increase of the endemic in Sub-Carpathian Russia, Poland, and Rumania, a decided increase in Yugoslavia, and a reappearance of the disease in Eastern Hungary, where only sporadic cases had occurred since the last epidemic of 1923-4. In Asia typhus showed an endemo-epidemic prevalence in Soviet Russia, with exacerbations in 1932, especially in Western Siberia, and in Persia. In Turkey it was on the decline in 1932, but showed an increase last year. In China, Manchuria, and Chosen the disease was present in endemo-sporadic form, whereas in Japan the disease did not succeed in taking root, only three cases occurring in 1932 and in 1933. Tropical typhus showed the same low incidence in the Malay Peninsula and Sumatra as in previous years. Sporadic cases of mild typhus were also met with in Australia, especially in the West. In the United States the marked increase in the incidence of endemic typhus, if not in the area covered by the disease, was mainly due to improvement in diagnosis. In Mexico the endemic, though severe, was practically stationary, if not on the decline. In South America, sporadic cases were notified in 1932 and 1933 in Venezuela and Argentina, but epidemics occurred in Peru, Bolivia, and especially in the central part of Chile. In Africa a serious epidemic took place in Lower Egypt in 1932 and 1933; the disease was also epidemic in the Constantine department of Algeria in 1933, and endemic in Morocco and Tunis, while in the Union of South Africa typhus has been definitely spreading during recent months, except in Cape Colony and Rhodesia, which has remained free from the disease.

THE SCREW-WORM BROUGHT TO BOOK

The question of myiasis, or the parasitism of human and animal tissue by the larvae of flies, is one of considerable interest in medicine. In most cases, the habit of invading actual living tissue is an optional one, practised as occasion arises by species which normally breed in dead and decaying animal material. The blow-fly group affords many instances of this, and the habit has even been put to practical use for surgical purposes in the United States and on the Continent. A similar but somewhat cruder practice has long been in vogue among the peons of South America to remove dead flesh from the backs of their horses. But some of the blow-fly group have become more strictly parasitic, and their larvae have become adapted to live only in living tissue. For many years *Cochliomyia macellaria* was regarded as such a species, and its larvae were known as "screw-worms." Recently, however, E. C. Cushing and W. S. Patton¹ have found that *C. macellaria* is probably a harmless fly, and that its misdeeds should be attributed to quite a different one, which they have called *C. americana*. Its larvae are the real "screw-worms," attacking living tissue and producing a true specific myiasis. That is the reason why it has so long remained undiscovered. The adults closely resemble *C. macellaria*, and so are likely to have been overlooked; the eggs are never laid in decaying meat, so that the usual breeding experiments would yield only adults of the harmless species. In addition to exculpating a relatively useful species from the stigma of compulsory parasitism, Cushing and Patton have pointed to the need for using an accurate microscopical technique in describing insects. The days when the hand lens was the entomologist's most important instrument are passing—albeit somewhat too slowly—and the classification of insects is becoming a much more scientific and accurate affair.

"THE MEDICAL, SICKNESS"

The fiftieth anniversary of the Medical, Sickness Annuity and Life Assurance Society, Ltd., is being celebrated by a dinner this week, and a pamphlet has been prepared for the occasion, giving a short history of this enterprise. It was Mr. Ernest Hart, Editor of the *British Medical Journal*, who first conceived the idea of a self-supporting mutual provident association that should provide for medical and dental practitioners a payment in the event of sickness, an annuity in old age, and a sum payable at death. Hart talked it over with various practitioners; he opened a discussion on the subject at a meeting of the British Medical Association, and through the columns of this *Journal* he was able to bring his project under the notice of many members of the profession. The society began work on March 1st, 1884, and by July 31st 540 members had joined. For over eight years the headquarters were in a private house in South London. In 1893 a one-room office was taken in Chancery Lane, but this was not big enough for meetings of the executive committee, which were held in one of the rooms of the British Medical Association in the Strand. Next year the members

numbered nearly 1,500, and the total funds were over £77,578. Ernest Hart resigned the chairmanship in favour of Dr. F. de Havilland Hall, who in 1912 was succeeded by Dr. F. J. Allan; he in turn was succeeded by the present chairman, Dr. F. C. Martley. In 1914 office accommodation was secured at Lincoln House, High Holborn, and during the war years the executive had to deal with many new and complex problems. In 1920 the status of the society was changed from that of a friendly society to a mutual company limited by guarantee under the Life Assurance Companies Acts. This required a new constitution, new rates, tables, and policies, and a modernization of all internal systems of business. Further rapid growth followed this change, which included the appointment of a board of directors instead of the old executive committee. By 1924 the membership was 4,111, the premium income nearly £54,000, and the total funds £391,000. Now in March, 1934, with a membership of 7,000, the funds exceed a million. The history told in this pamphlet passes lightly (for reasons that can be guessed) over the services rendered by Mr. Bertram Sutton, who began as "the solitary clerk" in the early 'nineties, then became assistant secretary, and since 1912 has been manager and secretary.

HOSPITAL DEVELOPMENT IN LONDON

The Metropolitan Counties Branch of the British Medical Association has arranged a meeting of the medical staffs of the London teaching hospitals to consider the problem of London's hospital development. It will be held at B.M.A. House, Tavistock Square, W.C., on Thursday, March 22nd, at 5 p.m., with Lord Horder in the chair. The discussion will be opened by Dr. J. S. Fairbairn, president of the British College of Obstetricians and Gynaecologists, Sir Crisp English, Mr. V. Zachary Cope, and Dr. Geoffrey Evans. It is hoped that there will be a full and representative attendance. A leaflet dealing particularly with the Hospital Policy of the British Medical Association as it concerns London has been prepared for the occasion.

HASTINGS POPULAR LECTURE

The sixth of the series of Sir Charles Hastings Popular Lectures, arranged by the British Medical Association, will be given in the Great Hall of the Association's House in London on Wednesday evening next, March 7th, by Dr. Robert Hutchison, whose subject is "The Food of the Growing Child." The chair will be taken at 8 o'clock by Lord Horder, and after the lecture relevant questions, in writing, are invited. Admission is free, by tickets obtainable on application to the Financial Secretary, B.M.A. House, Tavistock Square, W.C.1. Seats not occupied by ticket holders by 7.50 p.m. will be available for other members of the public.

The subject chosen by the British Orthopaedic Association for the Robert Jones Prize and Gold Medal for 1933 was Pott's paraplegia. In accordance with the decision of the judges that the essays written by Mr. R. W. Butler and Mr. H. J. Seddon are of equal merit, the executive committee of the association has awarded a gold medal and prize of £50 to each of these successful candidates.

ONE HUNDRED AND SECOND ANNUAL MEETING
of the
British Medical Association
BOURNEMOUTH, 1934

THE one hundred and second Annual Meeting of the British Medical Association will be held in Bournemouth next summer. The Sectional Meetings for scientific and clinical work will be held on Wednesday, Thursday, and Friday, July 25th, 26th, and 27th, the morning sessions being given up to discussions and the reading of papers, and the afternoon to demonstrations. The Annual Representative Meeting for the transaction of medico-political business will begin on the previous Friday, July 20th. The full list of presidents, vice-presidents, and honorary secretaries of the sixteen Scientific Sections, together with the provisional time-table, was published in the *Supplement* for January 27th. Other details of the arrangements for the Annual Meeting will appear in subsequent issues. We publish below the second of a series of descriptive and historical articles on the town and its medical institutions. The first, on Bournemouth and its attractions, appeared on January 6th (p. 22).

HOSPITALS AND BENEVOLENT INSTITUTIONS OF BOURNEMOUTH

The Royal Victoria and West Hants Hospital

General hospital provision for Bournemouth was first made in 1859 by the founding of the General Dispensary and Cottage Hospital in Madeira Road. In 1877 the Provident Dispensary was opened in Boscombe, and in 1882 the Boscombe Cottage Hospital was inaugurated. In 1889 the Royal Victoria Hospital at Poole Road was founded, and in the same year a dispensary for out-patients was opened in Holdenhurst Road. In 1897 a new hospital, now the West Hants branch of this hospital, was opened in Shelley Road, Boscombe. Eventually, in 1911, an amalgamation, confirmed by Act of Parliament, was brought about between the Royal Victoria Hospital in Poole Road (now sixty-eight beds), and the West Hants Hospital in Boscombe (now 168 beds), and the Royal Victoria and West Hants Hospital, of which His Majesty the King is Patron, came into existence. Recently a very fine hospital of fifty-eight beds for private patients of moderate means was completed as an extension of the Boscombe branch; it comprises all that is newest and best in hospital planning and construction.

This, the general hospital of Bournemouth, provides for the county borough and a wide area of adjacent Hampshire and Dorset, and is administered by a board of management. Except for cases of infectious fever and of acute mental disorder, all types are admitted for care and treatment, and the hospital forms a unit complete in all departments. Thirty-five cots are set aside for children; four beds for venereal disease cases; sixteen for maternity patients, the hospital now being recognized by the Midwives Board as a training centre for midwives; two for incipient mental cases; eight for ear, nose, and throat patients; and beds are available for surgical and complicated cases of tuberculosis, and, as necessary, for orthopaedic cases, patients with puerperal fever, and for cases of ophthalmia neonatorum. The special departments are complete, each being in charge of a specialist in his particular subject. The resident staff consists of a medical officer, a casualty officer, and four house-surgeons. Recently, large improved laboratories have been built and equipped for the departments of pathology, bacteriology, and biochemistry; and new spacious post-mortem examination rooms have been completed.

Although a large sum of money had to be raised during the year for capital expenditure, chiefly upon the private ward block, the generosity of supporters has enabled the hospital to pay its way. The increasing population of Bournemouth (117,000), and the ever-widening radius

served by the hospital, mean a continual pressure upon the accommodation available, so that every effort has to be made to extend both in-patient and out-patient departments. In the near future steps are to be taken to add forty-six extra beds, and to build further operating theatre accommodation, and additional quarters for the nursing staff. Last year (1933), the total number of in-patients was 4,745, while out-patient attendances totalled 111,616. The daily average number of in-patients was 230.48, and the average duration of stay 17.73 days. The number of surgical operations was 5,659, and of casualties 7,895. The total ordinary expenditure was £42,435.

Cornelia and East Dorset Hospital, Poole

Also a general hospital and the largest in the county of Dorset, this hospital serves the borough of Poole and the whole of East Dorset, and draws a considerable number of patients from other parts of the county. It was founded in Poole forty-five years ago, and at first had accommodation for thirty in-patients. Since then numerous additions have been made, so that now the beds and cots number 110. Last year a new operating theatre was added, and a new block for maternity patients is nearing completion. There is accommodation for eleven private patients, each of whom is admitted on the recommendation of his medical adviser under the care of a member of the honorary medical or surgical staff. Thirty-five years ago the number of in-patients was 231; last year the figure exceeded 1,500. The number of operations performed was 1,400. During 1933, 26,000 attendances of out-patients were registered.

The Royal National Sanatorium for Consumption and Diseases of the Chest

This hospital, of which His Majesty the King is Patron, is, as its name implies, a national institution, and is supported by voluntary contributions. Accommodation is provided for ninety-three patients of both sexes, who are drawn from all parts of the kingdom. Preference is given to those with early disease. The minimal age for treatment is 16. This sanatorium, built in 1855, is the oldest of the local charitable institutions and, by its establishment at that time, did much to popularize Bournemouth as a health resort. It is situated in Bourne Avenue on rising ground in the centre of the town, and faces south, being well protected from north and east by the shelter of its position and by the many surrounding pine trees.

The objects of the institution are: "To afford an asylum for patients afflicted with chest diseases who, being convalescent, may yet require further medical treatment and change of air to establish their health, or may be labouring under such incipient form of disease as to afford reasonable hope of their obtaining benefit from temporary residence in a dry and salubrious climate." This institution was one of the successful pioneers in the campaign against tuberculosis.

The Firs Home

The Firs Home, Trinity Road, was established in 1868, and is administered by a board of trustees and a committee of management. It admits patients with advanced pulmonary tuberculosis only, and has accommodation for twenty cases: ten male and ten female. Eight beds are retained by the Bournemouth Corporation. It is an interesting fact that this hospital was one of the first established for the specific purpose of caring for incurable cases of pulmonary tuberculosis. Until 1913 the home was maintained entirely by voluntary subscriptions. Since then patients have been received under the terms of the Health Insurance Acts, and latterly others have been admitted referred by public bodies under tuberculosis treatment schemes.

The Victoria Home for Crippled Children

This home, situated in Burnaby Road, Alum Chine, was first opened in 1898. Since then it has been enlarged several times. A branch of the Shaftesbury Society and Ragged School Union, the home is controlled by the council of the society, assisted by a committee of Bournemouth residents. There is room for seventy-three cripple children of 2 to 10 years, who are admitted for prolonged periods, and are given skilled nursing along with electrical, sunlight, and massage treatment. Children suffering from various types of paralysis, surgical tuberculosis, diseases of bones and joints, rickets, and deformity are admitted. As to relative numbers, those

suffering from paralyses head the list. The usual length of stay is three to twelve months. The home is certified by the Board of Education and approved by the Ministry of Health for the reception of selected cripple children referred by local authorities.

The Herbert Convalescent Home

This convalescent home in Alumhurst Road, Westbourne, was established in 1851 for the benefit of patients from Salisbury Infirmary, and for other necessitous sick persons recommended by the governors of the Infirmary, to which the home is attached in perpetuity. Patients admitted are those already convalescent and in no further need of any special medical or surgical attention. The tuberculous are not admitted. A committee of management of Bournemouth subscribers appointed at the annual Court of the Salisbury Infirmary meets quarterly, and administers the institution. There are sixty beds available, and the patients come from all parts of England. The duration of stay is a fortnight, but this period may be extended at the discretion of the committee. It is interesting to know that the original building in Alumhurst Road was planned by Florence Nightingale.

THE ROYAL VICTORIA BRANCH, POOLE ROAD

The Russell Cotes Home and School of Recovery

Opened in 1922, and recently enlarged, this institution at Parkstone, Dorset, accommodates 117 children of both sexes, with the necessary staff. The home is really a residential school of recovery for children of 7 to 14 who are debilitated, anaemic, or crippled, and who are selected by the school medical officers of the various London education authorities as being most in need of change of air and surroundings. Some twelve different metropolitan educational authorities send subnormal children to the home. Each child spends six weeks under care and treatment; a few remain for twelve weeks. Situated among pine trees on Constitution Hill, overlooking Poole Harbour and Brownsea Island, the

home grounds cover over ten acres of hillside, which King Edward was heard to declare afforded "one of the finest views in the kingdom."

Douglas House

Douglas House, in West Southbourne, was opened in 1924 by the United Services Fund as a convalescent and holiday home for tuberculous ex-service men of the Army and Royal Air Force. It was established for men with quiescent tuberculosis who needed a period of convalescence under medical supervision so as to render them fit for employment. Preference is given to men with sputum negative for the tubercle bacillus. The home is not a sanatorium or a training colony, but is designed to give a few weeks' seaside holiday combined with a regime suitable for the tuberculous. Up to October 31st, 1933, the total admissions numbered 5,326; the yearly average number of residents being 583. The total number of beds available is eighty, the daily number occupied sixty-one. The average stay of each patient is five weeks; the average gain in weight $2\frac{1}{2}$ lb. There is a resident medical superintendent and one assistant superintendent, a matron, a trained nursing sister, a male nurse, six attendants (exclusive of kitchen staff), and one housekeeper. An admirable arrangement exists whereby the Fund gives a money grant towards the support of a man's family while he is at the home.

Hahnemann Convalescent Home and Dispensary

Founded in 1879, this home was enlarged in 1883, and in 1914 a chapel was added. There are thirty-two beds for patients of both sexes, and ample balcony accommodation. Those eligible for admission are patients with incipient tuberculosis and convalescents from hospitals and dispensaries requiring rest and medical supervision, and they are admitted on a governor's recommendation, which is valid for twelve weeks' residence. Patients with any infectious fever, bronchitis, or bronchial asthma are not admitted. Males under 17 and females under 15 are not eligible for admission. The dispensary was originally established for the sick poor not receiving parochial relief: such were entitled to advice and medicinal remedies.

The House Beautiful

This was opened in 1894 for the reception of the many delicate children recovering from illness and in need of special care and attention. Eligible children are those convalescent after illness, or injury, or surgical operation. Girls between the ages of 6 and 14, and boys between 6 and 12, are admitted. When possible, the children are kept until they are completely restored to health.

MUNICIPAL HOSPITALS

The Infectious Fever Hospital at Gloucester Road (78 beds) is available for all cases of notifiable infectious disease, and, where beds permit, for those not notifiable but believed by the medical officer of health to be best segregated. The management is in the hands of the Health Committee of the Borough Council. With a rapidly increasing population this hospital no longer affords sufficient accommodation for all the cases which demand isolation. Present and future needs, however, are being considered so that a modern hospital, with room for necessary expansion, is likely to be built on an extensive site on the outskirts of the town.

The Small-pox Hospital at West Howe is situated within the borough, about three miles from the centre of the town, near to the Bournemouth, Poole, and Ringwood crossroads. There is accommodation for six patients only; but since the site is an extensive one any emergency can be met by the erection of temporary wards. This hospital also is managed by the Health Committee.

Fairmile House, Christchurch, serves the area of the former Bournemouth and Christchurch Union, and now, by agreement with the Hampshire County Council, is controlled by the Public Assistance Committee of the Bournemouth County Borough Council. There are avail-

able 276 beds for the admission of all patients, whether chronically sick (medical or surgical), venereal, tuberculous, maternity, borderline mental patients, or the mentally deficient; and there is accommodation for patients who need temporary isolation. No provision is made for out-patients or for those requiring operative surgical treatment. There is no resident medical officer, a part-time medical man in active medical practice being responsible for the medical care of all patients—an arrangement which has worked so far efficiently and well.

S. W. S.

A CONSPECTUS OF GENERAL MEDICINE

WELLCOME MUSEUM OF MEDICAL SCIENCE

There is a tendency for intensive specialization to cramp the field of medical vision. Its growth has been largely dependent upon the rapid progress in knowledge which has taken place during the last few decades; no man can be expected to become familiar with all the newer methods of diagnosis, clinical investigation, and treatment. In technical skill specialization finds its fullest justification; even games such as cricket and football have acknowledged this need, and the building up of an international side nowadays calls for a carefully balanced choice of specialists in different departments of the game. But the "all-rounder" in medicine, as in sport, is a man to be relied upon.

"TROPICAL" AND "NON-TROPICAL" DISEASE

There is one medical specialty which, in spite of its obvious advantages, involves special dangers—namely, tropical medicine. There are very few diseases which are strictly tropical. Malaria was at one time common in this country; during the Great War many cases occurred, not always among those who had returned from tropical or subtropical climates. Yellow fever has in the past occurred at European ports. Plague is a constant menace to shipping, and port authorities have to be alive to this ever-present danger; country districts in England have been attacked within living memory, and the history of Europe has been changed by calamitous epidemics of this disease. Yaws, which might with more justification be labelled a tropical disease, is so closely linked up with syphilis that it cannot be neglected by practitioners in temperate countries. Climatic bubo, or lymphogranuloma inguinale, is now classified as a sixth venereal disease, and may occur anywhere. Helminthic diseases, which are well taught at the tropical schools in London, Liverpool, and elsewhere, are largely neglected in the general medical curriculum. Possibly recent work on epilepsy due to cysticercus infection will do something to remedy this. Relapsing fever, bacillary dysentery, typhus, undulant or Mediterranean fever, leprosy, and many other diseases which have, in the past, been regarded as especially suitable for textbooks on tropical medicine are more a question of environment and social conditions than of climate.

To take the argument a stage further, increasing facilities for rapid transport are daily bringing within our reach diseases of which the average medical student has little knowledge. As an example of this may be mentioned schistosomiasis, which will shortly be a possible danger to the "week-end" visitor to Egypt.

It is essential to eliminate from the minds of medical men this arbitrary distinction between "tropical" and "non-tropical" diseases. In this way alone will it be possible to avoid such calamitous diagnostic errors as, for instance, regarding amoebic dysentery as tuberculous ulceration of the intestine, sleeping sickness as Hodgkin's disease, schistosomiasis as malignant disease of the

bladder, kala-azar as Banti's disease, yellow fever as Weil's disease, leprosy as ringworm, or the reverse.

ARRANGEMENT OF THE MUSEUM

The Wellcome Museum of Medical Science is designed to provide a comprehensive review of the medicine both of tropical and of temperate climates in such a way that, without unduly encroaching upon the time demanded by the regular curriculum, a student may obtain this broader view of medicine.

The museum is arranged on an aetiological basis, and thus, even from a rapid survey of the various sections, the visitor is able to orientate his conception of medicine as a whole. Commencing with the protozoal diseases, he passes to the metazoal, and so on to virus diseases, bacterial diseases, endocrine diseases, deficiency diseases, and diseases of mixed or unknown origin. Special sections are devoted to blood diseases, nerve diseases, skin diseases, and new growths.

In its method of display the museum differs radically from the classical medical museum, which is mainly pathological. Each disease is considered as a whole—*aetiology, pathology, symptomatology, treatment, and prevention*. By means of photographs, charts, drawings, models, and specimens it is possible to study each disease visually, and in such a way that the memory is stimulated and the interest sustained. It makes the student observe and reflect, it provides a ready means of revision, it supplies the busy practitioner with a reference museum where he can polish up any therapeutic or diagnostic weapon which has tended to rust through disuse. Most emphatically it is not "spoon-feeding."

Every effort is made to keep the museum up to date. The short descriptions of each disease, labels, illustrations, and specimens are constantly being revised. As the museum is becoming better known, specialists in the various subjects are giving generous assistance in its development. In each section files are kept in which are placed classified cuttings from the journals on the more recent work. These are kept up to date daily, so that a piece of important new work appearing in a journal one week will be found in the museum files before the next number has appeared.

FUTURE DEVELOPMENTS

The museum has already been visited by representative medical men from more than twenty different countries, and all have borne generous testimony to its national and international value. At present it is in process of development. Such an ambitious scheme will, of necessity, take many years to perfect; indeed, it is doubtful if finality can ever be reached, for the art of medicine is ever moving forward. Stagnation is the curse of most museums. It is only in the realization of its shortcomings that a museum can find salvation. Every visitor becomes a factor in its development by his suggestions and constructive criticism. It is hoped that the medical profession will support the scheme by taking a sympathetic interest in its progress; that teachers will bring their classes and use the various sections for demonstration purposes; that students—and especially senior students—will extend their range of knowledge by making free use of its facilities.

The museum owes its inception to the scientific enthusiasm of its founder, Sir Henry Wellcome, and its foundations were laid by that great apostle of hygiene, Sir Andrew Balfour. Their object can only be achieved when it has become a living force in medical education. The address of the Wellcome Museum of Medical Science is 183, Euston Road, London, N.W.1, and the director is Dr. S. H. Daukes.

England and Wales

Liverpool Medical School Centenary

This year (writes a correspondent) the Liverpool Medical School celebrates its centenary, for, although there are records of ship surgeons training in the town in 1789, it was not until 1834 that the Liverpool Royal Institution Medical School (as it was then called) was founded. Tales have been handed down from those early days of a camouflaged dissecting room within the precincts of a respectable boarding school for young gentlemen. How hastily did the scandalized parents remove their offspring when the news leaked out. The students at this time did four years dispensing and dressing in the wards, taking a final year in London, and, as the nursing staff was totally inadequate, they were probably far more adept in dealing with the drugs and dressings than are modern students, who tend to watch deft nurses doing the job. In 1845 the Royal Infirmary and the Medical School joined to form Queen's College, and the same year the Northern Hospital came into existence. A few years later the present Southern Hospital was built to complete the trio. The charter of University College was granted in 1881 and the Medical School became a faculty of the University. In the ensuing years the nucleus of the Gynaecological-Obstetrical Museum was collected, and much valuable work was done in all departments. The new century found the tropical medicine department outgrowing its quarters, until it had to break off and form a school of its own. During these years, also, the pioneer work in orthopaedic surgery brought honour to the school from all quarters. The medical students have added their quota to history. There are records of a famous "hot-pot supper," which lasted from Friday evening to Saturday afternoon. In 1874 the Medical Students' Debating Society was formed, and it exists to-day as the oldest and most flourishing society of the University. Under its auspices the students are arranging a medical ball to celebrate the centenary. This is to be held in the Adelphi Hotel, Liverpool, on Wednesday, March 14th. Lord Horder will be the guest of honour. The students hope that all who have an interest in the Liverpool Medical School will come and help to make the function a great success. Details and tickets may be obtained from Miss M. F. Procter, honorary secretary, Medical Students' Debating Society, the Medical School, University of Liverpool.

Small-pox in England and Wales

In a recent communication¹ to the permanent committee of the International Office of Public Health Sir George Buchanan states that the number of cases of small-pox notified in England and Wales decidedly decreased in 1933, and that the disease was tending to disappear from London and the South of England. Since the *Tuscania* episode in 1929 there has been no evidence of cases of variola major due to importation of the disease, nor, if one may judge by the clinical features and fatality rate among unvaccinated persons, has there been any increase in the gravity of the cases. During the period 1922-32 the deaths from small-pox in England and Wales, exclusive of the *Tuscania* cases, were 242 among 79,780 cases notified. It is impossible to state the exact number of uncomplicated cases of small-pox among these 242 deaths, or the number of cases in which the cause of death had nothing to do with concurrent small-pox, although small-pox figures on the death certificate in accordance with the regulations.

¹ *Bull. Off. Internat. d'Hyg. Publ.*, January, 1934, p. 52.

Out-patients at Guy's Hospital

A report on out-patient statistics for 1933, just presented to the house committee of Guy's Hospital, includes a table showing the number of visits made per out-patient in the various departments. That the out-patient department of the hospital as a whole is now being used more and more in a consultative capacity is indicated by the small number of visits made to the department by each individual out-patient. Taking the general average over all sections of the department throughout the year, the number of visits per out-patient works out at 2.6. This suggests that in a large proportion of cases patients are sent by their private or panel doctors to get the benefit of examination and consideration of their cases by the visiting specialists at the hospital, and then return to their own doctors to continue treatment in the light of the advice given them. For six months of 1933 a detailed record was made of the visits of patients attending the out-patient physicians. It was found that 69 per cent. of these patients attended only once or twice (the second visit being almost invariably for the result of an x-ray or other examination being recorded), 15 per cent. attended for two to five times, and 16 per cent. attended more than five times.

St. Pancras House Improvement Society

The ninth anniversary of the St. Pancras House Improvement Society was celebrated a few weeks ago. There has been in the past twelve months another considerable extension of the society's activities. Last year a large block of property with frontage on Seymour Street, including the offices of the society, came into the market, and the committee was faced with the alternatives of increasing its commitments or of allowing a closely populated area to be exploited by commercial development. There was a balance in hand of £16,000 towards the purchase price, and the remainder required—namely, £22,000—was subscribed in three weeks. The new site covers one and a half acres, and has been housing 700 inhabitants. During the last twelve months two other sites in the neighbourhood have been taken over for commercial purposes, and it was felt, therefore, to be essential that a special effort should be made to preserve the Drummond Street site for housing. Generous help in the way of donations and investments during 1933 has enabled the society to go forward steadily. An illustrated pamphlet has been issued by the society indicating the amount of building which has been accomplished since 1924 and the slum conditions which have thus been replaced by healthy homes.

Tuberculosis Returns

The Minister of Health has issued a circular (1368) to county and county borough councils, tuberculosis joint committees, and the authorities of sanatoria and other residential institutions, approved for the treatment of tuberculosis in England, with reference to the furnishing of annual returns. It has been found that the value of Part G of the annual return, which relates to the immediate results of the treatment of definitely tuberculous patients in residential institutions, has been seriously impaired during recent years by the inclusion of a considerable number of patients who remain in an institution for a few days only, and who may be readmitted several times during the year. This defect is stated to be most pronounced in areas where such patients who were previously in Poor Law institutions are now accommodated in public health hospitals, and are accordingly included in Part G of the annual return. The Minister has decided, therefore, to amend Part G so as to exclude from its scope all patients whose stay in residential

institutions has not exceeded twenty-eight days. For the year 1934 and onwards the form described in Part G of the first schedule to Memorandum 37/T (revised) will be amended so as to relate only to patients who have been discharged from approved residential institutions after a continuous period of treatment exceeding twenty-eight days. The second section of Part D of the first schedule to the Memorandum (in which short-stay patients should continue to be included) will be subdivided so as to distinguish the numbers of pulmonary and non-pulmonary patients, in order that information may be available as to the total numbers of pulmonary and of non-pulmonary patients dealt with in residential institutions during the year. The Minister does not anticipate that any variation in the records kept in pursuance of paragraph 2 of Memorandum 37/T (revised) by tuberculosis officers and the medical officers of residential institutions approved by him for the treatment of tuberculosis will ordinarily be needed to enable the annual returns for 1934 and future years to be prepared in the amended form now prescribed. This alteration of the requirements of the Memorandum became effective on January 1st; the returns for 1933 are not affected. The necessary changes will be made in the forms to be issued towards the end of 1934 for the purpose of the return for this year.

Scotland

Glasgow Royal Maternity and Women's Hospital

The annual medical reports of the Glasgow Royal Maternity and Women's Hospital illustrate the value of the standard scheme for unifying the clinical reports of maternity hospitals which was drawn up by the committee appointed by the Royal Society of Medicine. The seventh of these reports, for the year 1932, is exceptionally comprehensive, a new case sheet having been designed for the purpose of obtaining more detailed records. The institution, which is solely devoted to maternity cases, contains 175 beds, seventy-eight being reserved for ante-natal cases, seventy-eight for lying-in cases, and nineteen for "suspect" cases. These last are situated in an isolation block, under the charge of one of the assistant obstetric surgeons, who holds the post for four months at a time, assisted by a special house-surgeon, neither of whom during their tenure of office have any dealings with patients in other parts of the hospital. Such cases as those of "failed forceps" or of manipulation before admission are sent direct to the isolation block. Septic cases are transferred to the city fever hospitals. The remainder of the institution is conducted on the permanent unit system, each unit being staffed by a chief obstetric surgeon, a visiting obstetric surgeon, two assistant obstetric surgeons, and one extra assistant obstetric surgeon. During 1932, 4,391 patients were admitted, the average daily number of in-patients being 164. The average length of stay of patients in the wards was 13.6 days. The number of children born in the institution was 3,137, 2,740 (87 per cent.) being born alive. During the year there were eighty-two maternal deaths, a mortality of 1.8 per cent. A working agreement with the Corporation of Glasgow has enabled the hospital to continue its policy of not refusing treatment to any woman in labour, without overcrowding the wards. In 1932 the municipal hospitals received 1,022 patients as overflow cases. From the ante-natal dispensary, which is on the premises, many cases are admitted to the obstetrical department and to the ante-natal wards; in 1932 the number of patients treated in these wards was 1,561, representing 35.5 per cent. of all admissions. With this dispensary is combined a post-natal dispensary, and an infant con-

sultation (child welfare) centre; the total attendances at all these numbered 20,988 during the year. The hospital also conducts a large amount of obstetrical work in the patients' homes. Many patients are sent into its wards as emergency cases by general practitioners and midwives. In 1932 there were 2,873 abnormal cases—65 per cent. of all admissions. The prevalence of rickets in the population of Glasgow is responsible for this high proportion, and it is a factor that has to be borne in mind when comparing the morbidity and mortality figures with those of maternity institutions elsewhere. There were 213 cases of puerperal sepsis, and 235 of puerperal pyrexia. It was not found easy to apply to the hospital the simple division of cases into "booked" and "emergencies" suggested by the committee of the Royal Society of Medicine. For the purposes of this report three categories have been defined: patients who were under ante-natal supervision long enough to allow of the diagnosis and treatment of any abnormality which might be present; patients sent in as emergency cases by doctors or midwives, or by members of the hospital staff working on "the district"; and patients who had not been under ante-natal supervision. It will be noted that this classification is based upon the time during which the patient had been under supervision rather than upon the type of supervision. In the first category there were 2,940 cases; in the second 1,050; and in the third 401. From these figures it emerges that of a total of 4,391 patients treated in the wards of the hospital, 66.9 per cent. had had ante-natal supervision, 23.9 per cent. were sent in as emergency cases, and 9.1 per cent. were without recommendation of any kind.

Leith Hospital

At the annual meeting of contributors to Leith Hospital it was reported that the ordinary expenditure had exceeded the ordinary income by £4,284. During the year, however, sums amounting to £35,626 had been received in legacies. The amount received in subscriptions from the people of Leith and Edinburgh had been about £8,800; this was equivalent to about 2s. per head of the population of Leith. It was suggested that if the public could add another 1s. per head per annum, the difficulties of the hospital would be solved. The number of patients in the wards during the year had been 1,835, a decrease of 161 on the number for 1932. In the children's wing 810 patients had been treated, a decrease of seventy-two. The ordinary income had been £15,715, and the ordinary expenditure £19,999. Mr. David Bell was elected president of the hospital in succession to Mr. John A. Lindsay, who is retiring after twenty-five years' valuable service to the institution.

Training of Nurses in Municipal Hospitals

At a meeting of the Public Health Committee of Edinburgh Corporation on February 20th it was intimated by the medical officer of health that an application had been made to the General Nursing Council for recognition of the Western General Hospital, one of the municipal hospitals, as a training school for nurses. If this application were granted all nurses beginning at this hospital would be able to receive a complete training. Hitherto nurses in municipal hospitals had required to leave the city for one year in order to receive their training in surgical nursing. This incomplete training had reacted adversely on nurses applying for training in municipal hospitals, and to overcome this difficulty salaries had been paid to probationers in excess of those in other institutions. It was now proposed to reduce the salary scales for probationers to £20, rising to £40 per annum; this would effect a considerable saving, which would be utilized to increase the salaries paid to sisters, trained staff nurses, and matrons.

Aberdeen Post-graduate Course

The Aberdeen Medical School has arranged a course of post-graduate study at the Aberdeen Royal Infirmary and the Royal Aberdeen Hospital for Sick Children, on Tuesdays and Thursdays, at 3.15 p.m., from May 1st to June 14th, both dates inclusive. In order to enable practitioners if possible, to attend the complete course of instruction, the lectures and demonstrations given on Tuesdays will be repeated on Thursdays. The fee for the course will be £3 3s. Those desiring to take part in it should notify Mr. H. J. Butchart, secretary of the University, Aberdeen, not later than April 27th.

Springfield Asylum at Cupar

At a meeting of the Fife County Council Finance Committee, held at Cupar on February 14th, the question of an extension of the Joint Asylum at Springfield, estimated to cost £100,000, was considered. At a previous meeting, held on January 3rd, an adverse report upon the institution by the Board of Control had been discussed. This report had pointed out that the county of Fife had no institution for the mentally defective, and that the presence of mentally defective children in the same institution as mentally deranged children was detrimental to the recovery of the latter. It was also pointed out that the institution was overcrowded, that the accommodation for the nursing staff was too small, that the hospital conditions for the mental patients were unsatisfactory, and that there was no building specially devoted to worship for the 900 resident patients. Unless these matters were improved, the report continued, the Board of Control would be compelled to take action. The meeting on February 14th included delegates from Dunfermline and Kirkcaldy Town Councils, Perth County Council, and members of the Joint Asylum Committee. It was decided that there was a shortage of some 130 beds, that the hospital accommodation was too small, and that an operating theatre should be provided. It was resolved to proceed at once with the erection of a central kitchen at a cost of £5,000, and to recommend to the various councils concerned that the proposed extension scheme should be undertaken.

Victoria Infirmary, Glasgow

At the annual meeting of the Victoria Infirmary, Glasgow, Lord Provost A. B. Swan, who presided, said that the Infirmary required to meet an annual ordinary expenditure of £69,000; the figures for the past year had been satisfactory, although it would be desirable to have many more subscribers. Mr. William Gray, chairman of the governors, mentioned that the twelve principal voluntary hospitals in Glasgow provided 3,087 beds, and that during last year the number of patients treated had been 64,519, while in addition nearly 200,000 out-patients had attended the dispensaries. The cost of maintenance of these twelve hospitals had been £401,700 and the deficit on their maintenance accounts had amounted to £80,000, which had had to be met from legacies that ought to have been placed to capital account. The report of the Victoria Infirmary showed that the income had been £53,198 and the expenditure £69,186, leaving a deficit of £15,988 to be met out of the extraordinary income of £30,044. During the year the endowment fund had been increased by £15,290. The number of cases treated during the year, including those in the auxiliary hospital, had been 8,986. Extensions had been necessary, involving an expenditure of £23,000 for the paying patients' wing and £50,000 for the Nurses' Home. Accommodation would be provided in the section for paying patients for a further fifty beds.

Reports of Societies

VACCINATION: THE MODERN VIEW

At a meeting of the Section of Epidemiology of the Royal Society of Medicine on February 23rd, with Dr. J. D. ROLLESTON in the chair, a discussion took place on vaccination.

HISTORICAL

Dr. S. MONCKTON COPEMAN, in a historical and introductory address, mentioned that the actual word "vaccination" was not introduced by Jenner himself, but by a Dr. Dunning, of Plymouth Dock, who was evidently an enthusiast in the early days of vaccination. Indeed, in his inoculation of cow-pox as an efficient preventive of small-pox, Jenner apparently had been anticipated by Benjamin Jesty, who had vaccinated his wife and two children two years before Jenner made the experiment. It was Jenner, however, who compelled the world's acceptance of the truth of vaccination—a truth slow of realization, for although the outcome of an inquiry by the Royal College of Physicians on the subject was reported to the House of Commons in 1807, it was not until 1840 that the first legislative enactment was made whereby a non-obligatory vaccination was enabled to be carried out at the expense of the State. The Act of 1853 made vaccination compulsory, imposing penalties on parents and guardians for default. In the preparation of that enactment the old Epidemiological Society, the forerunner of the present Section, played a part of no small importance, as was acknowledged by Lord Lyttelton in presenting the Bill to the House of Lords. The next enactment was in 1867; this repealed the previous Acts, and gave very wide powers to Poor Law guardians. Evidence of opposition to the Act soon became apparent, and a Select Committee was set up, which declared in favour of obligatory vaccination but against the multiple penalties for default which had been imposed. The recommendations were incorporated in the Act of 1871. In 1889 a Royal Commission was set up, in view of the increasing opposition and resistance to vaccination; its report was not finally published until 1896, and some, not all, of its recommendations were embodied in the Act of 1898, including the introduction of the "conscience clause," the use of glycerinated calf lymph in place of the arm-to-arm procedure, and domiciliary vaccination. The speaker gave some account of the foundation of the Government lymph establishment, in which he had participated. Turning to the relationship of small-pox and vaccinia, Dr. Copeman said that the anti-vaccinationists had been accustomed to stress the absurdity of trying to protect against one disease by the inoculation of another, as they said, totally different disease. Yet, in coining the term "vaccinia," Jenner had seemed to have put on record his belief that small-pox and cow-pox were definitely related in some way, though, as Professor Greenwood had pointed out, down to the end of the nineteenth century vaccinia as a prophylactic rested solely upon an empirical basis. Dr. Copeman described his own experiments about 1902, which involved the passage of the variola virus through one or more monkeys from which calves were vaccinated, eventuating in the production of typical vaccinia. Public prejudice was aroused by the nature of the experiments, and it was ordered that all the strains of lymph should be destroyed; but before this order was made a number of children had been quite successfully vaccinated, and the experiments had proved decisive, as Professor Greenwood had also pointed out, on the point at issue. It was no longer possible for the anti-vaccinationist to claim that the two diseases were totally different. Of late years a change had come over the scene by the occurrence of variola minor. It had been suggested that in dealing with these outbreaks a policy of *laissez-faire* might be followed, which might have the result of protecting the exposed population. In view of the fact that practically all the small-pox of recent years had consisted of this mild type, and that the major type had been almost unknown in this country

for thirty years, the question of retaining compulsion had become more prominent. Another factor was the occurrence of post-vaccinal encephalitis. This was a condition which the Rolleston Committee had indicated, if certain measures advised in its report were followed, was likely to be of quite negligible importance. But in all the circumstances there would seem nowadays to be a fairly good case for the removal of the compulsory element from vaccination, provided always that the necessary administrative machinery was retained for possible emergencies.

SEROLOGY OF VACCINIA

Dr. MERVYN GORDON said that numerous studies had shown that, like the pathogenic bacteria, the vaccinia virus evoked the presence in the serum of specific antibodies. These were of three kinds: (1) a viricidal antibody that inactivated the virus *in vitro*, (2) a complement-fixing antibody, and (3) an antibody which produced a visible flocculation of the virus. Craigie had recently shown that this flocculation reaction included the action of both agglutinin and precipitin, and that the elementary bodies of vaccinia were the antigen concerned in it. Absorption experiments had proved that the antibodies present in the serum of animals hyperimmunized against vaccinia were equally specific for the viruses of vaccinia or variola major or minor. Antibodies evoked by vaccinia, therefore, could be applied in the diagnosis and treatment of small-pox. As regards diagnosis, the basis of the flocculation reaction for identifying material from cases of variola had been carefully and ably investigated by Tulloch and Craigie, and their observations were contained in two special reports to the Medical Research Council. They had shown that this specific flocculation test had definite practical value for identifying cases of variola and for distinguishing them from cases of varicella and other conditions. The specific treatment of small-pox with serum prepared against vaccinia had still to be tried. In their last report Tulloch and Craigie described some experimental observations on passive protection, which suggested that flocculating serum had valuable anti-infective properties, and these experiments, in the words of the introduction, "raise a hope that small-pox contacts might be passively immunized with a reasonable expectation that the disease would be aborted even in circumstances where vaccination might fail to prevent infection." In discussing cutaneous allergy to vaccinia, Dr. Gordon said that it was now widely recognized that the early skin reaction encountered on revaccination was specific, and it was also known that this reaction could still be obtained when the virus had been killed by heat. Wilson Smith had recently shown that a boiled extract of tissues heavily infected with vaccinia virus gave a specific precipitin reaction with immune serum, and also excited a specific allergic reaction in the skin of previously vaccinated subjects. Craigie, who had encountered a similar precipitable substance in Seitz filtrates of vaccinia virus, had then satisfied himself that this precipitable extract was nothing more or less than an extract of the elementary bodies. Accordingly, he undertook some field observations on skin sensitivity to these elementary bodies. The suspensions of elementary bodies were prepared from a rabbit strain of vaccinia virus, and were repeatedly washed and concentrated by centrifuge: the suspension which showed microscopically a very high degree of purity was then killed with formalin and carefully tested in order to prove that no living virus was left. With flocculating serum this suspension gave a positive result up to a dilution of 1 in 100. As intracutaneous injection even of the diluted suspension gave too severe reactions, he employed needle puncture through a drop of it placed on the skin. The observations were controlled by making tests in the same way with heated calf virus and living calf virus. The results were as follows: (1) of seventy-five individuals who had a history of vaccination and showed one or more scars, all reacted to the killed elementary bodies as well as to the living and dead calf virus, but by the seventh day all the former reactions had regressed, whereas in twelve cases the living virus lesion had progressed; (2) the next group consisted of fifty-two

individuals said not to have been previously vaccinated, and showing no scars on the arm. These all failed to react to the suspension of killed elementary bodies, and by the seventh day all showed a positive "take" with the living virus. Although the suspension of elementary bodies gave positive results in the previously vaccinated individuals, the Scitz filtrate of this suspension proved inert. The reactions, therefore, were due to the presence of the bodies themselves. Dr. Gordon concluded by presenting some photomicrographs which suggested that Bnust, who was public vaccinator in Edinburgh in 1887, had succeeded in showing the elementary bodies of vaccinia and variola.

EXPERIMENTAL WORK WITH THE VIRUSES

Professor J. C. G. LEDINGHAM recalled that five years ago he had opened a discussion on this same subject. At that time the new facts were the presence of a mild small-pox, which apparently first showed itself in 1922, and the recognition of post-vaccinal encephalitis as a possible sequel of vaccination. During the last five years the incidence of mild small-pox had fallen rather precipitately; the case mortality rate had risen from 1.4 to 4.2 per thousand, figures very similar to those recorded in the United States, where for thirty years the prevailing small-pox had been of the mild type, but very dissimilar from the Alexandria outbreak of 1932-3, which had a mortality rate of about 210 per thousand. The incidence of post-vaccinal encephalitis, which usually coincided in time and place with mass vaccination, had fallen to very small figures during the last five years. Coming to the nature of the viruses of small-pox and vaccinia, he said that knowledge had advanced very materially. By special methods it had been possible to secure the elementary bodies in pure suspension, and to show that such suspensions could be employed for agglutination tests with the sera of vaccinated animals. Similarly, prepared suspensions of elementary bodies extracted from the mild small-pox in England had also been shown to be agglutinable in the presence of serum from small-pox cases, and suspensions of varicella were agglutinated by the sera of chicken-pox cases and convalescents. The diagnosis of small-pox should no longer be regarded as the peculiar province of specially trained clinicians; the laboratory was now able to give valuable help in doubtful clinical cases. When the diagnosis rested between variola and varicella the serum of the case would in proper time make the diagnosis clear. The new knowledge must eventually revolutionize much of the technical procedure concerned with lymph production, culture on artificial media, and diagnosis. It would be necessary to employ for accurate experiment only the pure elementary bodies, and this was now an entirely practical proposition. There seemed to be good evidence that the bacteria-free lymph retained its potency for months or years. For the future there might be available bacteria-free lymph (1) grown in the chick embryo membrane; (2) grown in association with living cells or in media containing no living cells; and (3) pure suspensions of elementary bodies obtained by high-speed centrifugalization of filtrates of vaccinia. The period was fast drawing to a close throughout which vaccination against small-pox, the various cultures, and everything connected therewith had been surrounded with a cloak of mystery. The speaker also discussed the problem of post-vaccinal encephalitis in the light of further experience and recent experimental work on neurotropic viruses. It was doubtful whether there was any fresh information since the last discussion on this subject, but the problem must remain in the forefront of interest, and the hope of its solution a stimulus to more intensive investigation. The condition had not disappeared from this country, although the recorded figures had been very small. Information as to the condition in other European countries and the United States had been available for some time in the shape of reports of various national committees—Dutch, German, and Swedish, for instance. In Italy, which only a few years ago was thought to be free from this type of disturbance, there would appear to have occurred probably about 100 cases in ten years. In

the histological examination of fatal cases there had been practically no diversity of opinion, though certain authorities had felt constrained to ignore the characteristic histology of typical cases in their belief that the vaccinia virus was most likely to be the one and only cause. The search for an unknown virus must still proceed, and one encouraging sign was the realization that if one likely animal did not react to a suspected virus an unlikely animal might do so. With regard to vaccination practice, infant vaccination was rarely if ever followed by post-vaccinal nervous disturbance. The greater local and general disturbance following primary vaccination of young adults needed no emphasis. It was borne out again in a recent outbreak at Malmo, Sweden, where a number of cases of nervous disturbance had followed primary adult vaccination, not to speak of widespread complaints of sore arms. In spite of the fact that the Association of Public Vaccinators at their meeting in 1933 predicted the most lugubrious results if compulsory vaccination went—and with it the public vaccinator—he thought that the bulk of responsible opinion favoured abolition of the compulsory element, and the placing of vaccination on a free and voluntary basis, beginning with the infant, repeating at school age and early adult life, such a system to be supported by proper methods of education.

THE QUESTION OF COMPELSION

Dr. J. D. ROLLESTON said that he supposed he was in a minority in holding the view that vaccination should be compulsory. He only wished it could be made much more compulsory, and that the conscience clause could be abolished. Although he was too much of a cosmopolitan and anti-militarist to have much sympathy with the Nazi Government, he read with some satisfaction that the Prussian Minister of the Interior had issued an order that all anti-vaccination societies, including those which apparently existed among medical men, should be abolished, and that all anti-vaccination activities were forbidden. The reason why he held so strongly the view that vaccination should be compulsory was the comparative absence of small-pox throughout Europe. In countries like Bulgaria, Czechoslovakia, Austria, and Hungary, according to the last reports issued by the League of Nations, there was no case of small-pox at all, and in many other countries small-pox was only sporadic. This was due, of course, to the enforcement of vaccination. It was agreed that the present type of small-pox was very mild, and it was also urged that measures could at once be taken should the more severe type return; but the question was whether the measures would be taken in time. He reminded the members of the *Tuscum* incident of several years ago, when at least fifty-three cases were spread over the country; also the smaller but rather severe outbreaks of recent years in Willesden and Hendon. England was not alone in having the mild type. From 1921 to 1926 there was a similar mild outbreak in Switzerland, and it was interesting that in the German-speaking part of Switzerland, such as Basel, where vaccination was not compulsory, this small-pox, with some evidence of the more severe strain, was rife, whereas in French-speaking Switzerland—for example, Geneva and Lausanne—where vaccination was compulsory, there was comparatively little small-pox. Post-vaccinal encephalitis first became prominent in 1924, though there were isolated cases occurring earlier. He thought it was generally accepted now that vaccination was at any rate one factor in its causation. But it was essential to realize its extraordinary rarity; he had never himself seen a case. He also touched on the question of intracutaneous vaccination, about which a good deal had appeared in literature lately, especially in Austria. Many clinicians were in favour of performing intracutaneous vaccination, the chief reason apparently being that it did not leave a scar. The objections to it were that it seemed to be painful, the technique was more difficult, and it did not protect from encephalitis afterwards.

Dr. E. W. GOODALL said that it was generally recognized that encephalitis had grown up entirely of recent years, and it occurred not only after vaccination, but after small-

pox, chicken-pox, mumps, and rubella. As regards compulsory vaccination, he agreed with Dr. Rolleston. When one remembered that voluntary immunization against diphtheria did not seem to have gained much ground, in this country at any rate, it seemed unlikely that there would be a better vaccination against small-pox on a purely voluntary basis.

Dr. J. A. H. BRINCKER said that as an officer of a county council he himself had been drawn more and more to a conclusion against retaining compulsory vaccination. The psychology of the population had to be studied. As vaccination was now in the hands of the public health authorities they had the opportunity of dealing with it in a scientific way, and he thought the voluntary method was worth consideration. He wanted to know why variola minor should be so different from variola major. Had there been something in the evolution of the disease which rendered it of a milder character? Was the loss of its toxic properties due to some biochemical action?

Dr. R. P. GARROW said that it had been suggested that variola minor should be allowed to "rip"; the trouble was that it would not "rip." It was incapable of spreading furiously in a community and causing disfigurement, or even so high an incidence as to bring about inconvenience. He believed that at a previous discussion Professor Ledingham had said that variola minor was a fixed variant of small-pox. But what was a fixed variant of disease? Were not all infectious diseases fixed variants of something? It was true they were not all so closely related to one another as variola minor and variola major, but neither were diphtheria and scarlet fever so closely related as typhoid and paratyphoid. For practical purposes variola minor was a different disease, and that had been recognized now and the disease had obtained a separate name. But the position in this country was that although the dualist view prevailed in the literature, official and otherwise, nevertheless the official figures were presented as if the diseases were one, so that it was not possible to tell whether the deaths were due to variola major or variola minor. That was a state of confusion in which it was not easy to form definite views. With regard to vaccination, this was the best measure of prevention ever devised, but if it was a question of vaccination in relation to variola minor he was in agreement with those who definitely preferred to have the disease rather than the vaccination. About ten years ago it was asserted that London had an immunity from this mild disease, and London was held up as a marvellous example of administrative efficiency. For some years that was true, but a very different story had now to be told, for London, like every other town in which the disease had been well introduced, had a very good "salting," and neither vaccination, nor isolation, nor any other measure adopted had really stamped the disease out. At present, although the country in general was free from small-pox, London was still having from half a dozen to a dozen cases a week. The chief need in coming to a clear view on the question of vaccination was to make a distinction between the two diseases, and he was in favour of giving them names even more distinctive than variola major and variola minor.

Dr. COREMAN, in a brief reply, took up a point about generalized vaccinia, describing experiments which showed that the secondary vesicles contained the living virus just as much as the original vesicles at the point of vaccination. Dr. MERVYN GORDON answered a question about the flocculating serum; he said that it was obtained by Tulloch by immunizing rabbits against a virulent strain of vaccinia virus, and it was found that it gave good protection. These experiments had raised the hope that eventually it might be possible to apply passive immunity to small-pox contacts, so that even if they were vaccinated too late to prevent them from getting small-pox, by the administration of the immune serum they could be tided over. Professor LEDINGHAM said that the two things which had changed his view regarding compulsory vaccination were the recognition of post-vaccinal encephalitis and the fact that small-pox now in this country was of such a mild order. Post-vaccinal encephalitis was not a rare

disease; he thought about 1,000 cases had been recorded. He believed that variola minor was a fixed variant of small-pox, but the only evidence that it was a fixed variant was experience. There was cultural evidence from the bacteriological point of view that such variants did exist.

PROBLEMS OF FAT METABOLISM

At a pathological meeting of the Liverpool Medical Institution on February 15th Professor H. J. CHANNON read a paper on the dietary production and prevention of fatty livers.

Professor Channon gave an account of the researches of the Toronto school into the question of the prevention of the occurrence of fatty livers in depancreatized dogs maintained on a diet of lean meat and sugar and receiving an adequate daily amount of insulin. The earlier observations that the inclusion of fresh pancreas in the diet was preventive of this condition led to the later findings by Best and his collaborators that both lecithin and its constituent choline would prevent or cure fatty livers in diabetic animals. Subsequent researches by these workers showed that fatty livers could be induced in rats by feeding a diet of high fat content, and that these were prevented or cured by choline administration. The fatty liver in rats brought about by cholesterol feeding was likewise prevented by choline. Experiments carried out in collaboration with Best and Ridout with a view to further elucidating the preventive action of choline were described in some detail. Professor Channon then discussed the nature and amounts of the neutral fat, phosphatide, and cholesterol and its esters in the two types of fatty liver caused by diets of high fat content and containing cholesterol respectively, and considered the modifications from these constituents induced by the addition of choline to the diet. He referred to the mechanisms by which choline might exert its action, and to the possible clinical application of these laboratory findings.

The President suggested that in the results of Professor Channon's work there was possibly an explanation of the occasional failure of a ketogenic diet to relieve in epilepsy and in *B. coli* infection of the urinary tract, and a hint as to how such failure might be avoided. The speaker had not obtained the good results reported by others in the treatment of these states in children by ketogenic dietary, and they soon acquired a dislike of it and failed to thrive. It might be that the unfavourable effects of such dieting led to early disordered functioning of the liver, if not to actual fatty degeneration. The experimental results obtained by Professor Channon suggested that if lecithin or one of its derivatives was included in sufficient amount in the ketogenic diet the tendency to fatty degeneration would be controlled and the diet better tolerated.

Dr. HENRY COHEN welcomed the new avenue of approach which had been opened up to many problems in which disturbance of fat metabolism appeared to be associated with those endocrine disorders in which phosphatide depots seemed to be affected. He instanced the Achard-Thiers syndrome and pituitary basophilism. One fact the work described by Professor Channon did appear to establish was the advantage of a high carbohydrate-low fat diet in diabetes mellitus as opposed to a fat content of the diet as high as consistent with a suitable ketogenic-antiketogenic balance. The principle underlying the biological assay of choline—that is, by conversion into acetylcholine and measurement of its effect on the isolated rabbit's intestine—had been successfully used in the treatment of paralytic ileus in man.

The Mental After Care Association (founded 1879, Patron: H.R.H. The Prince of Wales) earnestly appeals for help to carry on and extend its work for recovered patients, and also for the early care of those suffering from nervous and mental illness, for whom it provides homes of recovery and expert care. Contributions gratefully received and further particulars given by the Secretary, Miss Vickers, Church House, Dean's Yard Westminster, S.W.1.

CORRESPONDENCE

Basal Narcosis in Anaesthesia

SIR,—In the most interesting paper by Dr. H. W. Featherstone in the *Journal* of February 24th (p. 322) there is an unfortunate printer's error in the figures of avertin administrations conducted by myself. I am stated to have given avertin in more than 12,000 cases, whereas the number which appeared in my letter to Dr. Featherstone was 1,240.

The same issue (p. 327) contains "A Warning Regarding Basal Narcotics," by Mr. R. J. McNeill Love, and in support of it he quotes a fatal case following the administration of avertin, which, in the summing up, he attributes to this drug, although in his introductory remarks he states that narcotics were "indubitably a contributory cause." There seems to be every reason for accepting the latter explanation, for the patient had received morphine grain 1/4 and hyoscine grain 1/100, the depressing effect of which on respiration must have been profound. I have drawn attention elsewhere (*Clinical Journal*, March 18th, 1931) to the all-important action of morphine in intensifying the action of avertin, and would wish to support Mr. McNeill Love's warning.—I am, etc.,

London, N.W.1, Feb. 24th.

FRANCIS E. SHIPWAY.

*. We much regret the misprint.—Ed. B.M.J.

SIR,—I am particularly interested in Mr. McNeill Love's article, and also in your leader on the same subject. It is time that the whole question of premedication before operation should be carefully considered. There is too great a tendency to-day to consider the wishes of a patient who has heard, either from friends or through the popular press, that insensibility can be produced before leaving the bedroom. For a long time now I have refused to allow premedication in my cases as a routine measure. Avertin is perhaps in a different category, and I must confess that I have at times succumbed to the pleadings of a patient. Premedication, either by barbiturates or even by doses of morphine, is unnecessary and sometimes dangerous. That such drugs assist the anaesthetist in getting the patient under cannot be gainsaid. This, however, is often offset by the alarm of shallow breathing—sometimes even cessation. It is, in my view, unfair to accede to a patient's desire for pre-anaesthetic medication without warning the patient first of the risk that is being run. The administration of any drug of value is accompanied by its own peculiar dangers. The potent drug that has no dangers has yet to be discovered. Premedication makes no provision for idiosyncrasy.

Anaesthetists look upon this question from a very different aspect from the surgeon. Their responsibility lies with getting the patient off the table. But patients are sometimes exceedingly ill after these premedicatory measures, and especially is this true in diseases such as exophthalmic goitre. The old-fashioned, very light, open ether—as practised and taught by my old teacher, Sir James Berry—is, I am convinced, the most satisfactory method in these cases. This is especially true to-day, when the operation is rendered so much safer by the previous administration of Lugol's solution. Of course, cases must be considered on their merits, and there are patients for whom premedication may be desirable; but I cannot believe that patients have changed so much in the last few years as to require the routine use of premedication before an operation can be satisfactorily performed. After all, it is for the anaesthetist, and not for the surgeon, to anaesthetize.—I am, etc.,

London, W.1, Feb. 23rd.

A. E. MORTIMER WOOLF.

SIR,—In the article by Mr. McNeill Love the death of a patient after an operation for a toxic goitre is attributed to the use of avertin for basal anaesthesia. It appears to us, however, that the facts as related in the article point to an entirely different conclusion.

It is well known that the combination of avertin with more than a very small dose of morphine and hyoscine introduces a real danger of respiratory depression. If not more than 1/8 grain of morphine is given the danger is almost non-existent; but the dose which Mr. McNeill Love's patient received—1/4 grain of morphine with 1/100 grain of hyoscine—was, in our opinion, almost certainly responsible for the failure of respiration. We believe that it is also wiser to reduce the strength of other drugs, such as novocain, in combination with avertin, and in our experience it is quite unnecessary to use novocain of a greater strength than 0.5 per cent., whereas this patient received 1 per cent. of novocain. It would also perhaps have been wiser to administer a carbon dioxide mixture rather than oxygen, if stimulation of the respiratory centre was required.

In our experience the administration of rectal avertin for operations upon patients with toxic goitre is a particularly safe form of basal narcosis, provided that the dosage of associated drugs is carefully regulated in accordance with knowledge of their action. Mr. McNeill Love observes that it is his practice to administer two-thirds of the official dose, and to supplement its effects with gas and oxygen. With the latter part of this observation we are in agreement, though it might be remarked that patients with a metabolic rate that is higher than normal are better able to deal with a full dose of avertin than individuals whose metabolic rate is normal. This constitutes an additional safeguard in using avertin as a basal narcotic in treating toxic goitre.—We are, etc.,

GEOFFREY KEYNES.

C. LANGTON HEWER.

London, W.1, Feb. 24th.

SIR,—The present attempts to assess the place of the barbiturates in therapeutics is of interest to all anaesthetists, in view of the wide differences of opinion displayed by experienced clinicians. There seems no doubt that these drugs can be dangerous. But so can morphine and chloroform in untrained hands, and no one refuses to use them on this account. By reason of accumulated experience we have learnt when to use them, in what doses, and, what is more important, when not to use them. In the case of the basal anaesthetics we have not yet reached this desideratum. Thus fatalities are attributed to their use which are due in reality to their misuse.

The article by Mr. McNeill Love fully illustrates this point. In the first of the two cases there described avertin was combined with an injection of 1/4 grain of morphine and 1/100 grain of hyoscine—a highly dangerous procedure. Moreover, the author states that he gave "4.4 c.c.m. of avertin, which is the recognized dose for a patient weighing 7 stone" (the italics are mine). Even with avertin there exists idiosyncrasy, and it is safer to regard the dose calculated according to body weight not as the recognized dose, but as the maximum dose. Satisfactory narcosis will often occur with two-thirds of the calculated dose, in which cases the calculated dose would constitute an overdose.

In the author's second case oral nembutal with 1/6 grain of morphine was combined with open ether. Here I only wish to point out that, since nembutal entirely masks the signs of anaesthesia, it is easy to give an overdose of ether using this method. I feel myself that, with nembutal, open ether unnecessarily increases the risk to the patient, and that nitrous oxide and oxygen, with such small

amounts of ether as may be necessary from time to time, is better.

It is only by articles such as that by Mr. McNeill Love that the profession will be enabled, by pooling its experience, to arrive at the correct technique for basal anaesthetics, the correct dosage, their indications and contraindications.—I am, etc.,

R. BLAIR GOULD.

London, W.1, Feb. 24th.

Medical Education

SIR,—With the general trend of Dr. Arnold Gregory's paper (*Supplement*, February 24th, p. 75) there will no doubt be general agreement. In some details, however, it seems to me open to criticism. I doubt, for example, whether it would be wise to spend less time in teaching students the signs and symptoms of disease in order to teach them something of the psychology of each individual patient. Psychology is a very difficult subject; a mere smattering of it would be of little or no practical value.

Sir James Mackenzie's work requires no recommendation; but can an undergraduate be expected to feel much interest in "the earliest deviations from the normal" or in incipient diseases until he has learned their classical features when fully developed? The general practitioner has this field of incipient diseases all to himself, but I am not aware that anything of much practical importance has resulted hitherto—nothing that an undergraduate might be expected to know. When he enters practice he will have almost daily opportunities of supplementing his standard textbooks.

Heating in mind that the educational problem of the moment is how to lighten the present curriculum, and at the same time turn out men with a better general education and better equipped for service to their patients, one doubts whether it is really necessary to stress the importance of purely clinical work. This may seem heterodox to some. But it goes without saying that facts ascertained by the unaided senses must always be the foundation on which a diagnosis is based. Every general practitioner has to employ his senses every day in clinical investigations, and if he employs them conscientiously he will automatically acquire in time "clinical instinct," more or less. The fact is that "clinical" work is imperative before and after graduation. What is not so imperative but, occasionally at any rate, more important is, for example, how to distinguish "the flu" from early pulmonary tuberculosis; a primary from a secondary anaemia; glycosuria from diabetes; a pneumococcal or streptococcal tonsillitis from diphtheria; or how to judge of the functional efficiency of the kidneys in a case of albuminuria. One might mention other common examples in which "the clinical instinct of the master clinician" usually requires to be supplemented. Can the general practitioner of the future be expected to apply up-to-date methods in arriving at important decisions in such common ailments as these, or must he continue to delegate all but purely "clinical" diagnosis to others?

I do not presume to answer this question, but I feel very strongly that every medical student should have a sound practical training in laboratory technique in so far as it is relevant to his future work. If he has such a training he may utilize it in after years, or he may not. But if his training is defective in this respect he will not acquire a laboratory technique in general practice automatically, as he will in some measure acquire a "clinical instinct," this being conditioned by experience and natural aptitude rather than by pre-graduate training.—I am, etc.,

Manchester, Feb. 26th.

J. STAVELY DICK.

Ovulation and Menstruation

SIR,—In his paper on ovulation and menstruation in the *British Medical Journal* of January 6th, Dr. Wilfred Shaw makes rather ungracious reference to the views which have been expressed by Corner, Hartman, and myself as to the possibility of anovulatory menstruation in the human female. He particularly seems to find fault with my own statement that the discussion as to what is meant by "menstruation" has become a "mere play on words," as I believe it to be. The time-honoured definition of menstruation is that it is a periodic physiologic bleeding from the uterine mucosa, occurring most often at about four-weekly intervals. That such a bleeding can occur without ovulation permits of no doubt, and it is not clinically distinguishable from the far more common ovulatory type. If Dr. Shaw knows of any method of making this distinction short of histological examination, we would all be grateful for the information. That the two types of menstruation present both histological and physiological differences we know as well as he, and I have repeatedly emphasized this point.

Every gynaecologist accepts the fact that functional menorrhagia, often very slight, and characteristically periodic, is not associated with ovulation. That in some women with normal periods ovulation does not occur I have shown by the examination of the mucosa just before the expected menstrual bleeding, and others have done the same. If Dr. Shaw would systematically study the premenstrual mucosa of sterile women in whom other causes of sterility have been eliminated, I feel sure that he likewise would find some instances of this sort. One would get the impression from Dr. Shaw's critique that we look upon this type of menstrual bleeding as common when exactly the reverse has been stated in my several papers touching upon the subject. The other viewpoint of menstruation is that it is a periodic uterine bleeding, dependent upon ovulation, and associated with characteristic post-ovulatory secretory changes in the endometrium. If Dr. Shaw likes this definition, the "American school," to which he makes such unkind reference, has no objection. It is this distinction which I designated as a "play on words," a mere matter of definition. There are other instances of anovulatory periodic bleeding which offer unimpeachable evidence on this point, such as, for example, the often typically menstrual bleeding seen with granulosa-cell tumours in very young children or in women far beyond the menopause. Here there is an abundance of the follicle hormone, with no ovulation or corpora lutea.

The whole subject of reproductive endocrinology is still too unsettled to justify any such dogmatic criticism as Dr. Shaw has indulged in. Many of us, for example, do not agree with him in some of his views, not always supported by scientific evidence, on uterine haemorrhage, and I feel sure that there will be no general agreement with the statement in his recent paper, based on a relatively small material, that "ovulation is restricted to about the fourteenth day of the cycle." Nor do I share his un-Whitmanian disdain for comparative studies, especially upon the monkey, from which we have already learned so much as to reproductive physiology. My own work, I should add, is, like that of Dr. Shaw, practically entirely with human material. There can be no objection to honest differences of opinion, but no worker in this field has as yet won the right to the oracular position which Dr. Shaw appears to have assumed in summarily waving aside the views of others no less anxious than he to arrive at the truth.—I am, etc.,

Baltimore, Md., U.S.A., Feb. 10th.

EMIL NOVAK.

A Milk Ration for Children

SIR,—I have read with interest the article in your issue of February 24th, in which you discuss the proposal of the Children's Minimum Committee "that a daily ration of fresh milk should be made available for all children attending State-aided schools, and for younger children through the Public Health Department." I agree that our use of the term "fresh" is ambiguous, and it has laid us open to a good deal of misunderstanding. It was intended simply to exclude dried and tinned milk, and had no reference to treatment of ordinary liquid milk before consumption.

The chairman refused to accept Sir Ernest Graham-Little's amendment that the words "pasteurized at a low temperature" should be substituted for "fresh," not because the committee is not alive to the dangers of infected milk, but because it does not feel, as a lay body, competent to lay down either the means or the standard of safety. To have accepted this amendment would have excluded raw milk produced under any conditions, and would also have excluded your own very useful suggestion that in places where it is not possible to obtain a supply of such milk safe for children, nor of properly pasteurized milk, that the milk should be boiled immediately before use. Many children dislike boiled milk, but the difficulty might be overcome by the addition of cocoa, etc.

On the one hand we have great numbers of children whose diets are deficient in the nutritive qualities which milk can give them, on the other we have a surplus of milk ready for their consumption, but produced under widely varying conditions and of very different qualities. Probably a certain amount of elasticity will have to be allowed in any practical scheme; in the large towns pasteurization may be the solution, and I think my committee would agree that in any case the responsibility should rest with the medical officers of health in the district to ensure that the milk supplied to the children is either of a sufficiently high quality to make it safe for consumption or is made safe by treatment.

The other measures which the committee is pressing upon the Government are: (1) That it should be made compulsory on local authorities to provide school meals for children who, by reason of the poverty of their parents, are inadequately fed. (2) That the allowances for the children of unemployed persons should be substantially increased. (3) That encouragement should be given to the extension on municipal housing estates of schemes of rent rebates where the family income is insufficient for minimum needs. We very much hope that we shall have the support of the medical profession in our efforts to secure for every child a minimum of healthy living.—I am, etc.,

MARJORIE E. GREEN,

Secretary, Children's Minimum
Organizing Committee.

116, Thames House, London,
S.W., Feb. 27th.

Is there a "Fourth Disease"?

SIR,—I suggest that the cases recorded by Dr. W. Lees Templeton in the *Journal* of February 24th (p. 358) may be explained without supposing a "fourth disease," in the usual definition of that term. That Case 1 was one of measles is proved by the occurrence of measles in the patient's sister, notwithstanding the absence of Koplik's spots, which are not to be observed in a small proportion of the cases of measles. The rash which was noticed on November 25th and 26th was one of the prodromal rashes so frequent in that affection. The case may also be regarded as a mixed infection of measles and Vincent's angina. But tonsillitis is occasionally present at the beginning of an attack of measles.

Case 2 appears to have been one of acute faucial inflammation (also with stomatitis) accompanied by a morbilliform erythema. Such cases are by no means rare. May I be allowed to refer to an illustration of an extreme example which will be found in my *Text Book of Infectious Diseases* (1928), p. 136?

Two other points are raised by Dr. Templeton's letter—namely, the value in diagnosis of (1) enlarged superficial lymph glands, and (2) desquamation. (1) These glands are not enlarged in all cases of rubella, but in about 75 per cent. Moreover, they may be enlarged in many cases of measles and scarlet fever. (2) Though scarlet fever is the disease in which peeling is most frequently seen, yet I have met with not a few cases of measles, rubella, and erythema other than that of scarlet fever which have been followed by the most profuse desquamation (see the above-mentioned book, p. 267).

May I add a word or two on the use of the term "fourth disease"? This name was first applied, tentatively, by Dr. Clement Dukes to that disease which the majority of clinicians believe to be a variety of rubella—namely, the scarlatiniform variety. Dukes was of the opinion that it was a quite different disease. But he would not have admitted under the heading of his "fourth disease" cases in which there were a "petechial rash on neck and clusters on the body," and "a patchy erythematous rash on body," or "a few scattered papules on neck and face, rough morbilliform eruption on buttocks, legs, and arms." The rash of "fourth disease," according to Dukes, was much more like that of scarlet fever than that of measles.—I am, etc.,

Hampstead, Feb. 25th.

E. W. GOODALL.

Pathogenesis of Cancer

SIR.—Mr. Frank T. Paul's letter under the above heading in the *Journal* of February 24th is a most welcome contribution, as it indicates a line of approach in our investigation of the cancer problem which I am afraid has been rather overlooked by most of our pathologists up to now. After drawing attention to the fact that, when one kidney is removed, the other one grows to about double its size and then stops, he goes on to state that "Surely it can only be due to a somewhat similar though erratic call that causes a tissue to reproduce itself in the abnormal form of a new growth." Now that mysterious erratic call which, when it comes to a cell, forces it to grow and proliferate at a rate out of all proportion to that of the normal cells around, with results disastrous to the host, is really the elusive factor we have been so long seeking; in fact, it is the alpha and omega of the pathology of cancer. Let us once discover its nature and the manner in which it works, and the great cancer problem is solved.

Cytologists have done much for us in explaining what actually happens in the cell during that complex series of changes collectively known as mitosis. Geneticists have extended our knowledge immensely when they demonstrated that the chromosomes are made up of small units called genes, which determine the form which the future individual will take. And the biochemists have done their part nobly in isolating numerous catalytic or activating substances which have been proved to be capable of exerting definite specific actions on the cells, and to cause them to respond in various ways. But, notwithstanding this progress, there yet seems to be something seriously wanting, either in the co-ordination of the work which is being done by the different branches or in the opening up of new lines of approach. We may know all about the changes which take place in the cell during its life, we may know all about chromosomes and genes, but unless we understand the dynamics of the cell and

know all that is to be known of the forces which bring about these changes, our knowledge is incomplete and the problem will remain unsolved.

An intellectual savage, finding a motor car with an empty petrol tank abandoned in the wilderness, might possibly take the car to pieces and examine the cylinders, pistons, crank-shaft, clutch, etc., and, being an intelligent savage, he might say to himself, "If these parts could only be got to move, this car might take me to the next village"; but yet he would be at a complete loss as to how he could get the car to go. To him it would be a dead thing, as dead, in fact, as far as he was concerned, as the tumours which we have preserved in our museums. Are we not also only intelligent savages, concentrating our attentions on dead machines and wondering how they go?

The unfertilized mammalian ovum, if it does not meet with an appropriate spermatozoon, will lie dormant indefinitely and never undergo further change; in other words, it is like the motor car which our savage found in the wilderness. If, however, a friendly spermatozoon were to come along and push his head through the zona striata, then the whole mechanism would come to life at once as if by magic. Growth and cell division would immediately start on a gigantic scale, and in no time a new organism would be taking definite shape. Biologists tell us that each of the cells (ovum and spermatozoon) possesses a complete set of factors necessary for the development of the organism, but neither of them can start developing until it unites with the other. The force necessary to put the different parts of the mechanism into motion in the kinetic state at least does not come into existence until the gametes join to form the zygote. It has usually been held that the spermatozoon brings in that force element in the shape of the centrosome, but I think it is much more probable that the element in question is a complex one, consisting of two complementary entities; and as one of these exists in the ovum and the other in the spermatozoon, neither of the cells can by itself proceed to further development, and until union occurs the ovum will remain a mere static individual.

Biochemists have recently not only succeeded in isolating several substances which have been proved to exert definite specific actions on living cells and to cause them to respond in various ways, but they have also succeeded in manufacturing some of these substances synthetically, and Sir Frederick Gowland Hopkins, in his presidential address before the British Association last year, stated that it has now been definitely established that there is a distinct group connexion chemically between such substances as vitamin D, oestrin, and a cancer-producing substance. Are we now at last on the eve of great discoveries? Be that as it may, we are much in the debt of the biochemists for having given us a most promising and valuable lead, and it is up to our leaders now to see that properly co-ordinated team work is started forthwith, and that both the dynamics of the cell and the forces which operate within it are thoroughly investigated.—I am, etc.,

Harrold, Bedfordshire, Feb. 25th.

E. G. FENTON.

SIR.—Mr. Frank T. Paul, in his letter published on February 24th, states his conviction that cancer is much more common among the highly civilized races than in those leading a natural wild life. This agrees with the well-substantiated reports of McCarrison, Hallilay, and others, who have proved the high degree of immunity from cancer (and from many other diseases) of the alimentary tract of certain tribes that live on a healthy "natural" diet and earn it by hard physical work in the

open air. The people of Hunza afford an instance of this, fully reported by Sir Robert McCarrison (*Practitioner*, January, 1925, and elsewhere); the total cancer incidence among the people of Hunza is negligible.

It is agreed, I take it, that the undoubted increase in the cancer rate of recent years among civilized races is due almost solely to cancer of the digestive organs. Moreover, Dr. W. Cramer (*Lancet*, January 6th, 1934) insists that it is the alimentary tract that provides the great bulk of the cancer of civilized countries, yet he scarcely even hints at the prominent part that our highly sophisticated diet may play (I should like to say *must* play) in producing the susceptibility to cancer to which he refers throughout his paper. Mr. Paul, on the other hand, is fully alive to this influence of diet.

In my presidential address to the Hunterian Society on "Stasis and the Prevention of Cancer" (*British Medical Journal*, December 25th, 1920), and more fully in Chapter XX of my book *Chronic Intestinal Stasis: A Radiological Study*, I give facts and reasons that seem to me conclusive for the view that susceptibility to cancer is brought about ordinarily by long-continued fouling of the blood stream by the products of intestinal putrefaction. Thus every cell of every tissue and organ is affected adversely and its resistance to disease impaired. Anyone who, like myself, is engaged daily in the x-ray investigation of disorders of the digestive organs can testify to the extreme frequency of pathological changes in the stomach and intestines due to bacterial action. It is not possible within the limits of a letter to describe in detail the changes that occur and the manner in which those changes lead to cancer, but I would commend the matter very earnestly to the consideration of all who are interested in, and more particularly of those who are actually working upon the causation and prevention of cancer.—I am, etc.,

ALFRED C. JORDAN,
M.D., M.R.C.P., D.M.R.E.

London, W.1, Feb. 23rd.

SIR.—I am in entire agreement with my fellow student, Dr. Mitchell Stevens, when he says that cancer is a deficiency disease, but I differ from him when he says the deficiency is entirely in the food. I have found that all cases of industrial cancer occur only in workers who have been exposed for a prolonged period (fifteen to twenty years) to a certain amount of CO gas. CO gas; by its powerful attraction for haemoglobin, displaces a certain amount of the oxygen, and consequently less oxygen is circulated to the tissue cells. A reduced supply of oxygen tends to lower the vitality of the cells and to reduce their capacity for recuperation after prolonged irritation. Only a certain percentage of the workers develop industrial cancer, and those most prone are the ones who are fed on preserved foreign foods from which the oxygen has been driven out.

The blood of men of 55 years of age and upwards in whom a senile anaemia is present has its oxygen-carrying capacity reduced, and this reduction explains their complete immunity from the disease in "carcinogenic" factories from 15 until 55. This reduction of the oxygen-carrying capacity tends to move the pH of the blood towards the acid side, and as a result renders the blood more liable to flocculation by a chemical or bacterial catalyst. This flocculation in the skin areas interferes with the metabolic rate of these cells, and so gives rise to a modified form of their growth in, for example, the form of a "pitch wart." I dealt with this problem very thoroughly in the *Medical Press and Circular* for August 30th, September 6th, and September 20th, 1933.—I am, etc.,

Swansea, Feb. 25th.

G. ARBOUR STEPHENS.

Treatment of Compound Fracture

SIR,—Mr. Simpson-Smith's interesting article on the open reduction of compound fractures (*British Medical Journal*, 1933, ii, 1019) induces me to raise the question of open *versus* closed treatment of fractures once more.

In the early years of this century Arbuthnot Lane evolved a technique for the open reduction of fractures which was far in advance of anything at that time, and which produced correspondingly good results in his hands. Lane's methods dropped into disfavour owing to the occasional intervention of sepsis, but we have arrived at a period in the development of surgical technique when this can be excluded. If the open technique of fracture reduction gives quicker satisfactory results, then it should be used. Meanwhile the closed method has been making headway, and we claim at this hospital to have evolved a technique whereby limb fractures can be reduced and fixed in position on the day of admission. This is the very essence of successful fracture treatment, and no open operation can do more.

With regard to compound fractures of the tibia and fibula, the wound is excised and sewn up, and immediate extension applied with the leg on a frame. An unpadded plaster cast is applied, leaving a window over the wound, and the limb is then transferred to a splint with the extension still operating. This method has the advantage over Mr. Simpson-Smith's of avoiding an operation which, however carefully carried out, must to some extent interfere with the vascular supply of the tissues and thus delay healing. The acid test of fracture treatment is the time which elapses before the patient can return to work. We have found that for thirty-five consecutive fractures, whether simple or compound, the time taken was three and a half months. This is two weeks longer than Mr. Simpson-Smith's treatment, but I feel this is justified in view of the fact that, not only have we eliminated an operation which must further traumatize already damaged tissues, but also we have one technique which is equally applicable to simple or compound fractures.—I am, etc.,

Southend-on-Sea General
Hospital, Feb. 19th.

ALAN PHILIPS, F.R.C.S.,
Resident Medical Officer.

The Tuberculosis Problem

SIR,—Dr. Gordon Tippet, in the *Journal* of January 19th (p. 76), invites the attention of the medical profession to the prevention of tuberculosis; and "A. R. F." (February 3rd, p. 214) indicates some of the deficiencies of the tuberculosis service as it functions to-day, and as I described it in the *British Journal of Tuberculosis* in 1924 (October, p. 149).

There is a tuberculosis sanatorium of over 100 beds, situated some twenty miles from the city that maintains it (with which I was connected from its foundation), which has no x-ray plant and no modern laboratories or equipment for "collapse" therapy and other modern forms of treatment. Its waiting list is long and the period of treatment relatively short. There is a city tuberculosis dispensary where the radiographs are interpreted by a non-medical assistant (as the medical officer is not a radiologist), and where modern forms of treatment are neglected. Its sessions for diagnosis and treatment are very limited in number and duration, though it serves a population of well over 200,000.

There is no attempt made generally to offer facilities for the separation of "contacts" (even children) from the infective member of the household at the routine "contacts" examinations (throughout the country). Dr. G. Gregory Kayne (*Journal*, 1933, ii, 1231) quotes the Canadian and French (dating from 1904 onwards) evidence

of the value of separation of the infant and child from the source of contagion at home. (See also Bushnell, F. G., *British Medical Journal*, November 14th, 1925, and *The Medical Officer*, September 22nd, 1923, p. 142.) Only a few lucky patients obtain after-care in a "village settlement," and, whether "open" or "closed" cases, they return from sanatorium to former home and workshop conditions. An "after-care colony" which I helped to found is now reserved for ex-service patients, and the civilian is excluded because he has no "living" income.

In July, 1924, the Senior Medical Officer of the Ministry of Health wrote that these "after-care" schemes were "being carefully watched by the Ministry of Health," as there "was not yet sufficient experience to enable a sound or final decision to be taken." The great majority of patients with advanced disease die at home, despite the Minister's statement of policy. During sickness the patient, whether insured or not, is not given an adequate income to live on. The "extra nourishment" grants improved sanitary, housing conditions, employment, etc. are delegated too often to a voluntary care committee and to the helpless tuberculosis medical officer; in other words, these problems are most inadequately dealt with or are shelved.

If a consumptive woman becomes pregnant she is confined at home, or at the local infirmary, if lucky; but no special accommodation is provided or specific precautions taken, or, indeed, advice given, before, during, or after childbirth to help the mother or save the infant from infection, as in France.

Inspections of tuberculosis dispensaries and sanatoria etc., are perfunctory. Refresher courses for the medical officers and nurses are seldom afforded or availed of.—I am, etc.,

London, S.E.1, Feb. 16th.

F. G. BUSHNELL.

SIR,—The efficiency of the tuberculosis service cannot be much further improved as long as it is tied to its narrow specialism. When the young enthusiast for diseases of the chest enrolls in the tuberculosis service he soon finds that his interest in the patient must be strictly limited to tuberculosis, and in consequence his interest flags and his real use as a specialist in all chest diseases is not utilized. Is it not just as important to the State, for example, that a child or a man suffering from lobar pneumonia should be returned to the family without complications as to decide whether the case is one of tuberculosis or not?

At present many practitioners attempt to use the tuberculosis service for non-tuberculous cases by calling in the tuberculosis officer and saying: "I don't think this case is one of tuberculosis, but I should like your advice." In how many of these cases is the T.O. able to use his knowledge to the full? If the case is found not to be one of tuberculosis, but is one for hospital treatment, he sees no more of the case. The general practitioner has frequently to exercise considerable tact in introducing a T.O. to a patient. Patients hate the name tuberculosis, and in consequence they dread the T.O.'s visit. The result is that the practitioner often attempts a diagnosis of tuberculosis on his own without the T.O.'s specialist resources, and is compelled only at the last moment to call in the T.O. when the case has proved too difficult.

Efficiency in the service could be greatly improved by: (1) making the T.O. a consultant in, and available for help in, treatment of diseases of the chest generally; (2) adapting superfluous bed accommodation in sanatoria for diseases of the chest other than tuberculosis, due attention, of course, being paid to segregation from the tuberculous; and (3) eliminating the names tuberculosis

dispensary and tuberculosis officer. These methods could in many cases be accomplished if the T.O.'s services were utilized as those of a consultant at the county hospitals.—I am, etc.,

NORMAN J. ENGLAND,
Assistant Tuberculosis Officer.

Boston, Lincs, Feb. 19th.

SIR,—Early diagnosis is, of course, essential, and under an efficient anti-tuberculosis scheme one may take it for granted that the necessary ability and means are at hand for this purpose. But we know that under present economic conditions the working man and woman do not come at an early stage of the disease, so that there remains the chronic invalidism from which arises the menace of infection to the rest of the community. Here is the crux of the problem, and it is in the control of the spread of infection that our tuberculosis schemes are inadequate. There is but little legislative control, one's hands are tied, and one has to watch the case infecting all those around him at home and in the factory. We are not even allowed to protect the babies, and in this connexion it is about time that a well-controlled B.C.G. campaign was considered, whatever the attitude of the Ministry. The tuberculosis problem can only be solved by stronger legislative measures, by the insistence on the removal of a positive case for treatment and isolation when in a chronic stage in State-controlled colonies, by control of contacts, and by a system of compensation for dependants and also for loss of work so as to eliminate factory infection. One cannot elaborate this in a short note, but if it sounds drastic or "expensive" then one can only point out that millions have been spent on schemes that are hopelessly inadequate for the purpose for which they have been inaugurated.—I am, etc.,

Birmingham, Feb. 16th.

J. S. D.

Sudden Circulatory Failure and Diabetic Coma

SIR,—Dr. Douthwaite's reply, in the *Journal* of February 24th (p. 353), to our letter appearing in the issue of February 17th, has, we think, missed the essential point of our communication. We did not seek to stress the platitude that "circulatory failure . . . precedes death in coma," but to call attention to a matter of direct clinical importance—namely, that particular precautions may be usefully taken to lessen the danger of sudden death from such failure. In our letter it was pointed out that this fatal collapse in our patients was precipitated by elevation to the sitting posture, and, further, that in two of our three cases the failure was effectively treated by laying the patient flat in bed.

In the first and second of our cases it was only by cross-examination of the sister in charge that the fact was established of the patient having been moved prior to the collapse. Unless we had previously noted this fact in our third case described, we might not have asked for information regarding movement, and we should have remained in ignorance of the essential cause of the sudden circulatory failure. We think anyone who has had hospital experience will agree that, unless nurses are specifically ordered not to move a patient, it will not occur to them that it may be harmful to move a patient on to a bed-pan or to raise him so as to adjust the pillows. We therefore suggest that it would be most helpful if Dr. Douthwaite inquired into the events preceding the deaths of his four patients in order to see if he can elicit any information regarding unauthorized movement shortly before the fatal termination.—We are, etc.,

C. J. FULLER,

Royal Devon and Exeter Hospital, Exeter.

H. P. HIMSWORTH,

February 26th. Medical Unit, University College Hospital.

Painless Injections

SIR,—With reference to the recent correspondence in the *Journal* on painless (hypodermic) injections, I take the liberty to draw your attention to "a useful hypodermic outfit" described by me in the *Indian Medical Gazette* of January, 1925.

The outfit consists of an all-glass hypodermic syringe provided with a platino-iridium needle. The syringe and needle are in the first instance sterilized by boiling, and only boiled or sterilized solutions are afterwards used in the syringe. To wash out the syringe after use, and at the same time to maintain it constantly in sterile condition, as well as to prevent the piston from sticking to the barrel, a mixture of equal parts of glycerin of carbolic acid and rectified spirit is carried in a small bottle, and five to six minims of this mixture are drawn into the barrel of the syringe on each occasion after use. The piston is then slowly withdrawn while the nozzle of the syringe is held upwards, in order that the fluid may escape and that the whole syringe may at the same time be washed out and lubricated before replacing the piston. An attenuated layer of the mixture is thus left in the syringe, from which the spirit rapidly disappears by evaporation.

Experience shows that the amount of glycerin and carbolic acid left in the syringe causes no irritation on injection, but the syringe may be washed out before use with a teaspoonful of water freshly boiled over a spirit lamp. Hypodermic tablets are in all cases dissolved by boiling over a spirit lamp in the requisite amount of water in a teaspoon. The platino-iridium needle is sterilized by heating in the flame of a spirit lamp immediately before and after use.

Experience over many years has proved that with this outfit, which is constantly ready, sterile and painless injections can be given in a minimum of time.—I am, etc.,

Cairo, Feb. 11th.

J. WALKER TOMBS.

SIR,—In a sense I appreciate the point raised by Dr. Leak that even relatively septic hypodermic injections as a rule cause no trouble. I am not able to give him actual instances of the nature which he seeks, but I do know of one instance in which a syringe had been used for aspirating pus, subsequently found to contain *B. welchii*, which on later use for serum conveyed *welchii* infection to another patient. The danger of infection from organisms in the air may be remote. At the same time, he makes his query as a scientific man, and my answer to this is that the most scientific thing one can do, in the interests of one's patients, is to avoid all possible danger, and yet to give injections as painlessly as is practicable. Others may differ, but I have merely mentioned my own methods, as I believe them to be absolutely safe. It is better to be safe than sorry.—I am, etc.,

London, S.E.5, Feb. 26th. GUY BOUSFIELD, M.D. Lond.

* * This correspondence is now closed.—ED., B.M.J.

Gas and Oxygen Anaesthesia

SIR,—Dr. Chalmers, in your issue of February 17th, refers to the cost of gas and oxygen anaesthesia, and mentions that for teeth extraction ether or chloroform is still much employed.

I am using a small portable gas and oxygen outfit supplied by Messrs. King and Co., London, which I understand was built to the specification of Dr. de Caux of London. The flow of gas is intermittent, and is administered by a nosepiece. The oxygen is led direct to the nose. With the mouth packed by a pad of gamgee tissue to which a tape is attached, there is rarely any difficulty in getting the patient to breathe regularly through the nose. In many cases it is unnecessary to administer oxygen, occasional breaths of air being sufficient.

I have used the nasal method of gas administration in over one hundred cases, and find it an inexpensive anaesthetic. A 100-gallon cylinder of N_2O costs 9s., and it is sufficient for three or four average extractions. In many cases thirty-two teeth have been removed at one sitting, and the duration of anaesthesia has been up to fifteen minutes. The great advantage in dental work is that the mouth-pack prevents inhalation of blood or teeth. The absence of nausea or sickness, and the rapid recovery from the anaesthetic, are further advantages, which are appreciated by the patient and the dentist.—I am, etc.,

Edinburgh, Feb. 19th. A. G. CRUIKSHANK, M.R.C.P.Ed.

Treatment of Influenza

SIR,—I have read with great interest Dr. James Torrens's article on influenza in the *Journal* of February 17th, (p. 274). I am glad to say that during the last thirty years I have successfully treated a large number of cases of post-influenzal debility by a modification of Swedish treatment. The first chief object of this, in the condition mentioned, is to try to restore the diminution of sensation in the cerebro-spinal nerves, this being largely effected by means of the "nerve frictions" of Kellgren; and the second object is to remove hypotension or hypertension, so often found in the posterior cervical muscles. I can confidently recommend the method, details of which were published by me in the *British Journal of Physical Medicine* for 1932 (p. 65).—I am, etc.,

London, W.1, Feb. 20th.

EDGAR CYRIAN.

Tonsillectomy: Complete or Partial?

SIR,—Since removal, both partial and complete, of the tonsils is now so very frequently and widely practised, it may be opportune, and perhaps of some interest, to raise the question as to the relative value of these two methods of treatment. Given diseased tonsils and the necessity for surgical intervention, it would seem that the only rational procedure is complete removal by dissection, whereas partial removal by the guillotine only is wholly illogical, inadequate, and of questionable usefulness, calling, maybe, for further operative intervention later on. Is complete removal on all possible occasions the ideal to be aimed at? That is the question I would ask, and the opinions of other of your readers will be appreciated.—I am, etc.,

H. W. FREER, M.R.C.S., L.R.C.P.

Birmingham, Feb. 20th.

Left-sided Stance for Urethral Instrumentation

SIR,—In connexion with my memorandum in the *Journal* of December 30th, 1933 (p. 1211), and the letters of Lieut.-Colonel Novis and Mr. Alex. Roche in your issue of January 13th (p. 78), may I suggest that I mentioned that both the surgeon's forearms or elbows could be rested on the front of his thighs. A further advantage is that they and his hands are in a line with the shaft of the instrument instead of being at an angle. I can quite understand that simplification is unnecessary for a surgeon of the skill and experience of Colonel Novis.

The advantage of the left-sided stance for the passing of catheters or bougies is that, while the skilled right hand manipulates the instrument, the left hand, in cases of difficulty, is available for rectal examination and control—a safeguard which no careful surgeon will neglect. I may add that patients in whom prostatectomy might

be risky can be submitted to litholapaxy without danger to life. Should there be some enlargement of the prostate the method which I have indicated does simplify the picking up of pieces from the floor of the bladder in cases in which the method of depression and opening of the blades of the lithotrite has failed.—I am, etc.,

Srinagar, Kashmir, Feb. 19th.

ERNEST F. NEVE.

Veiled Advertisement of Abortifacients

SIR,—I enclose a catalogue which I gather is sent by a "surgical stores" in Glasgow to all parents (and perhaps others) who announce a birth in the *Times*. Lord Dawson's Bill for the control of sale and advertisement of contraceptives will no doubt save unmarried people from receiving such aids to promiscuity; but what of the married folk who are unable, for one reason or another, to obtain reliable advice on "birth control"?

On page 27 of this catalogue we find advertised: "Special double strength occasional pills for ladies, recommended by eminent physicians, for anaemia, and all kindred ladies' ailments and irregularities. Prompt and safe in action. Relieve where others fail. Specially recommended for stubborn cases." At the side these pills are stated to be "prepared with apiol, steel, pennyroyal, and bitter apple. Harmless, but prompt in action where others fail." Thus these thinly disguised abortifacients are offered to the lay public. One can easily imagine a young wife, distracted to desperation by a day or two's delay in the onset of her menstruation, taking twice, three times, nay, even a hundred times, the advertised dose (for are they not "harmless"?), thereby seriously imperilling her life and future health. (1) Apiol has been reported as causing acute nephritis, dysenteric colitis, and sloughing endometritis; the B.P.C. describes it as an irritant to the genito-urinary tract. (2) Pennyroyal is a genito-urinary irritant (B.P.C.). (3) Bitter apple is a "powerful hydragogue cathartic; extremely irritant," and "partly absorbed and excreted by the kidneys" (B.P.C.).

I feel that the public is in need of protection from circularization with such dangerous and misleading advertisements. I shall be grateful if you will give such publicity to the matter as you may deem suitable to the end of bringing to light any similar "anaemia cures."—I am, etc.,

ALISTAIR R. FRENCH, M.R.C.S.

Greenford, Middlesex, Feb. 21st.

Medical Examination at the Police Station

SIR,—In Dr. Redmond Roche's letter in the *Journal* of February 24th (p. 358) with regard to the recent examples of judicial solicitude for persons charged with being under the influence of alcohol while in charge of mechanically propelled vehicles, no reference is made to the distinction between being "under the influence of drink" to such an extent that one is unfit to drive a car, and being "drunk" to such an extent that one is incapable of giving legal consent to medical examination. Sir E. Graham-Little, at a joint meeting of the Pedestrians' Association and the Cyclists' Touring Club, lately held to protest against the appalling increase in road accidents, emphasized the distinction between "drunkenness" and the less easily recognized effects of a small dose of alcohol; if this distinction is not yet recognized by the courts it ought to be.—I am, etc.,

London, N., Feb. 24th.

Medico-Legal

THE DUTIES OF THE MEDICAL WITNESS.—I

We print below the first of a series of five articles on the giving of medical evidence in courts of law, contributed by a legal correspondent.

INTRODUCTION

A doctor's calling makes him more liable than any other professional man, except perhaps a policeman, to be called upon to give evidence in a court of law. Some medical men are completely at home in the witness-box; they have for years held official positions, such as those of pathologist or analyst to the Home Office, in which it has been a part of their work to appear as witnesses for the Crown against persons accused of crime. Others, in increasing numbers nowadays, are constantly asked by insurance companies to examine persons who are making a claim for personal injury received in road accidents or at work, and to give evidence of their findings if the claim is pressed in court. The great majority of medical men, however, do not realize that a subpoena is an accident which may happen to a doctor any day without warning, and do not prepare themselves for this difficult and delicate work.

The giving of evidence in judicial proceedings is part of the doctor's work, and likely to become an increasingly important part of it. An action, trial, or inquest is a piece of constructive work in which judge, counsel, and witnesses have definite parts to play, and the medical witness's part is as important as any. It is a definite job with its own rules, and demanding a particular attitude, aptitude, and technique, which must be understood and learnt like those of any other job. The necessity for attending to this potential part of his work becomes obvious when a medical man considers how many possibilities exist which may call him to the witness-box whether he likes it or not. He may be called in to a patient who dies in such circumstances that he cannot see his way to signing the death certificate (for example, where the patient is suffering from injuries which may be due to violence or to an attempt at criminal abortion); he may be called to testify to the mental state of one of his patients years before; he may be summoned to give evidence in divorce or nullity proceedings when he has attended one of the parties to the suit; or he may be called by a workman patient who is claiming compensation, or by the victim of a motor-car collision who is suing the driver for damages.

To one unaccustomed to it the witness-box is a terrifying and unpleasant place, and the ordeal is especially formidable to the medical witness, because he is nearly always asked to go beyond the bare facts and give his opinion and his deductions from the facts. Counsel on the other side, in the interests of his clients, will quite properly do his utmost to discredit the medical witness and to lead him into admissions that may be taken to prove that he is wrong or ignorant. Every doctor is keenly conscious of his dignity and responsibility as a medical man, and it is just these qualities which the opposing counsel is most anxious to assail. If he succeeds, and makes a medical witness look ignorant or ridiculous, the witness is hurt and humiliated, not only in his personal pride, but in his professional honour. The public estimate of the medical profession is influenced very largely by the demeanour of medical men as witnesses. The professional and private conduct of a doctor in the ordinary course of practice is not obvious to the public eye, but in court it is open to the inspection of perhaps a hundred people directly and—in particularly unlucky cases—to thousands of people through the Press. A medical man is therefore acting most unwisely if he neglects to train himself in that attitude of mind which will do him credit in court, and to study the rules which govern this difficult duty.

THE NEED FOR PREPARATION

Few persons other than those concerned in the administration of the law realize how much important work has

to be done behind the scenes on a case of any kind before it is tried in court. A law case is rather like an iceberg: the visible part is very small compared with the vast bulk below the surface. Often the solicitors send to counsel at an early stage a "brief," or statement of the facts, usually accompanied by a file of correspondence, and ask him to advise on what evidence they should call. They then invite to their office, or send a clerk to, the witnesses he specifies, and make a "proof," or written summary, of the evidence which these persons are prepared to give in court. The proof is not on oath. Sometimes they ask a doctor to write them a report instead of making a proof. One of the saddest, but at the same time one of the commonest, events in the life of a lawyer is that a witness fails to "come up to proof"—that is, declines to say in the witness-box what he has said in the solicitor's office and on which great hopes may have been founded. An ordinary witness, possibly of little intelligence and more concerned to further the interests of one side than those of justice, may with a certain difficulty be excused for this shortcoming: a medical witness cannot be so excused. Like the lawyer's, most of his work is done before he goes into court. So important is it that he should prepare his evidence in every detail that in these articles his mental attitude, the language he shall use, and everything to which he should pay attention long before the hearing are dealt with before his actual receipt of the subpoena.

THE EXPERT WITNESS

Legally there are two kinds of witnesses: the ordinary witness, who gives evidence only of fact and whose opinions are not admitted; and the expert witness, whose duty is chiefly to give his opinion. The general rule of evidence is that the court wants to hear facts and not opinions, but a wide exception to this rule is that the opinion of an expert is admitted on matters of science, art, or skill—matters, in short, where special study and experience are necessary. He must have devoted sufficient time and study to the subject to make his evidence trustworthy. The judge decides on the competency of a witness to give evidence: the jury decides how much his evidence is worth when he has given it. Since every medical man has had a scientific training which qualifies him to give opinions, at any rate on an appreciable range of medical subjects, the distinction between the ordinary and the expert witness is not very material for him. Most medical witnesses are called as experts, but even when a medical man is primarily called as a witness to fact, as he often is in the coroner's court, he is nearly always asked to give an opinion on the facts which have been given in evidence, and so is treated for the time as an expert witness.

An expert witness, in order to amplify his opinion, may quote from books of admitted authority. He may read a passage and say, "That represents my view." He may also quote from reports of other cases and transactions which throw light on the facts in issue. For instance, if the witnesses to fact prove that a person has suffered from certain symptoms, the experts may cite cases in which the symptoms were similar, so that the jury may draw the inference that the causes and the symptoms in those cases were probably the causes and the symptoms in the case before them.

In *Rex v. Palmer* (5 E. and B. 1024), the Rugeley murder case, the Crown said that Cook, the dead man, had been poisoned by Palmer, and called medical experts to give evidence that the circumstances of his death pointed to poisoning by strychnine. They were not present at the death and could find few traces of poison in the corpse, but they quoted three other cases of persons who had been undoubtedly poisoned by strychnine, and showed that the deaths of these persons resembled that of Cook in almost every particular. The court admitted this evidence and Palmer was convicted.

Nevertheless, a medical man cannot merely read a book in the witness-box simply as evidence that the subject-matter is as stated—that is, as a substitute for the direct evidence of the author. When the question to be decided is whether another medical man has treated a particular case in a negligent manner, a witness cannot read from a medical book to show what treatment would have been

proper, though he may read a description of treatment and say, "I consider that to be the proper treatment."

In order to avoid an undignified collapse, a medical man who is to be called as an expert should not only take all pains to make himself familiar with the matters on which he is to speak, but should also by an effort of mind put himself in the position of hostile counsel, who will be anxious to cast disbelief and ridicule upon his evidence. Sir William Willcox¹ suggests that the witness should seriously cross-examine himself on every aspect of the question, and some writers recommend that he should seek out an argumentative medical friend and invite him to pull his evidence to pieces. He ought not to find this advice very difficult to follow. When he has found the weak points in his evidence, he should at once make them clear to the solicitors who are calling him. Even if the medical man is being called merely as a witness to fact, he will probably be treated as an expert (unpaid), and plied with questions on the general significance of the facts, involving hypothesis and probability. He should aim at knowing as much as a man in his particular kind of practice ought to know, but he need not go outside it—and, indeed, he will be very unwise if he does.

MEDICAL REPORTS

In many cases an expert witness, a considerable time before the hearing, is asked to furnish a report of the matters with which he is concerned.² He should send this report to the solicitors of the party calling him, and should be very careful to put nothing into it which he cannot substantiate in the witness-box. Sir William Willcox¹ tells of a famous murder trial in which the accused pleaded that he had been insane at the time of the murder. One of the medical witnesses, a mental expert, had given a very strong report saying that the prisoner was sane. When he saw an array of distinguished mental experts going into the witness-box and saying exactly the opposite, he felt weaker and weaker, and at last he said to the counsel for the Crown, "I am afraid I cannot say in the witness-box everything that I have said in my report." This put prosecuting counsel in rather an awkward position, and, needless to say, that expert was not called.

Sir John Collie,² a witness of vast experience in insurance cases, advises doctors to couch their reports in the most definite language, the simpler and less technical the better, any doubts being clearly stated. He adds a warning that, if the report is to contain anything very condemnatory—by which he probably means, for example, an expression of the doctor's opinion that a certain patient is malingering or behaving fraudulently—the doctor should write the report personally and not dictate it to a secretary. This precaution is advised to protect the doctor against a subsequent action for libel on the ground that the defamatory matter was "published" to a person in circumstances not protected by qualified privilege.³ Although the doctor may write anything he sees fit, so long as it is true and he writes it in good faith, to persons entitled by their interest in the matter to receive his report, the privilege does not cover the defamatory matter if it is published to some other person. If the doctor prepares the report with his own hand and writes the word "confidential" on the top and on the envelope, he is secure, and if the report is afterwards seen by some unauthorized person, the publication will be accidental and the doctor will not be open to an action.

When a coroner proposes to hold an inquest, and it appears to him that the deceased was attended by a qualified doctor, he can summon the doctor as a witness. If the deceased was not attended by a doctor, the coroner can summon any doctor in practice near by to give evidence how the deceased came to his death. He can also, either in his summons or at any later time until the inquest, direct the medical man to make a post-mortem examination. Similarly, if the coroner thinks that a post-mortem examination might make an inquest unnecessary,

he can direct any doctor whom he could summon as a medical witness to make such examination and report in writing. The doctor must obey the summons. Moreover, at any time after he has decided to hold an inquest, the coroner may request any qualified doctor to make a post-mortem examination, or do a special analysis or test, or make any other examination which the coroner thinks ought to be made. The doctor need not comply with the request, but if he does, and is summoned as a witness, he may be asked his opinion on any matter arising out of the examination and on the cause of death. If the coroner thinks that a necropsy will make an inquest unnecessary, he may request any doctor whom he could not summon as a witness to carry it out, and the doctor may consent or not as he pleases.

The general practitioner will do well not to forget that he may at any moment find himself called upon to perform a necropsy and make a report. If he is unaccustomed to the work he should read what Taylor and other well-known writers on medical jurisprudence have to say about it. He will, of course, use the greatest care in performing the examination and in writing his report, and bear in mind the possibility that he may have to undergo cross-examination at the inquest by a barrister instructed to support some contradictory view on the cause of death. He should use clear, simple language, and write nothing which he is not prepared to stand by in public.

(To be continued)

MURDER CHARGE AGAINST DOCTOR DISMISSED.

Dr. John Blakely was charged on February 12th at Sheffield with the murder of an unemployed waitress, who was found in a state of collapse near her home and died the same night from septicaemia following an abortion. After a speech for the defence at the adjourned hearing on February 21st the Sheffield magistrates dismissed the charges both of murder and of supplying a drug to the deceased girl knowing it to be intended for unlawful use. The presiding magistrate said that the evidence was so weak that no jury would convict.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The Faculty Board of Medicine has appointed Dr. W. L. H. Duckworth, Dr. A. E. Barclay, Dr. E. D. Adrian, Dr. A. N. Drury, and Dr. Eric Holmes to be members of the Degree Committee of that Faculty until January 31st, 1936.

Under the will of Mr. A. Marmaduke Sheild, M.B., F.R.C.S., formerly of Downing College and surgeon to St. George's Hospital, who died in 1922, provision was made for the founding of a scholarship in human anatomy of the annual value of £100. Regulations for the establishment of this Marmaduke Sheild Scholarship have now been drawn up by the Faculty Board of Medicine and will in due course come before the Senate for approval, the Financial Board and General Board offering no objection.

A bequest of £7,166 for the advancement of biological research in the aetiology and treatment of disease has been made to the Master and Fellows of Gonville and Caius College, under the will of Dr. Charles Percy Handson of Bromley, Kent.

At a congregation held on February 22nd the following medical degrees were conferred:

M.B., B.Chir.—C. W. Walker, D. W. Smithers, L. T. Bond.
M.B.—A. R. R. Le Fleming.
B.Chir.—W. I. Bain.

UNIVERSITY OF LONDON

At the meeting of the Senate on February 21st, with the vice-chancellor, Professor L. N. G. Filon, F.R.S., in the chair, Dr. R. J. Lythgoe was appointed to the University Readership in the Physiology of the Sense Organs (University College, as from October 1st, 1933).

The William Julius Mickle Fellowship for 1934 was awarded to Miss Lucy Wills, M.B., B.S.

The title of "Fellow of University College, London" was conferred on Dr. A. S. Parkes, F.R.S., a member of the staff of the National Institute for Medical Research, Mount Vernon, Hampstead, formerly Sharpey Scholar and honorary lecturer in physiology at University College. The title of "Honorary Fellow of University College, London" was conferred on Emeritus Professor Karl Pearson, F.R.S.

Obituary

J. F. DOBSON, M.S., F.R.C.S.

Consulting Surgeon, General Infirmary, Leeds

Mr. J. F. Dobson, the well-known Leeds surgeon, died on February 19th at the age of 60, after an illness of fluctuating severity for the preceding twelve months. He came of medical stock, his father, the late Joseph Dobson, M.D.Lond., having been one of the oldest and most respected practitioners of Leeds, predeceasing his son by a few years only.

Joseph Faulkner Dobson was medically educated at the University of Leeds (the Yorkshire College), and after qualifying in 1897 held post-graduate resident posts at the Leeds General Infirmary.

He was appointed assistant surgeon in 1905, full surgeon in 1913, and consulting surgeon in 1933. He was also consulting surgeon to the Batley and Ilkley Hospitals. He obtained the M.S.Lond. degree and the F.R.C.S.Eng. diploma in 1901, and delivered the Arris and Gale Lectures before the Royal College of Surgeons in 1907 and again in 1922. On the retirement of Lord Moynihan Mr. Dobson was appointed to the chair of

surgery in Leeds, and was honoured by the University with an emeritus professorship on the completion of his tenure of office. As a lecturer and clinical teacher he was held in great esteem by both junior and post-graduate students. To the former he was always a sympathetic friend, and to the latter he was a rich source of inspiration, both in surgical practice and in research. As head of the department of surgery in the University he felt a compulsion to explore systematically and directly the general range of the surgical theory and practice of his time, and was constant in his study-visits to almost every great surgical centre. He had in this respect a great sense of values, and sought always to incorporate the really usefully new into his own practice and the teaching of his own school.

As surgeon to the Leeds General Infirmary Mr. Dobson performed great and valuable work. Though his main work was probably in abdominal surgery, he was fully and efficiently an "all-round" surgeon, and always progressive. In later years he became a leading exponent of genito-urinary surgery, and it had always been his ambition to create a special department in this branch in Leeds. His war service was interrupted by the prolonged and serious cardiac illness which was later responsible for his premature death. At the opening of the war he was in charge, as administrator, of the 2nd Northern General Hospital, and was most resourceful in the difficult task of organization of a service strained to its utmost in the early months of its activities. After his recovery he went abroad to take charge of the surgical division of the General Hospital at St. Omer.

Mr. Dobson made many contributions to medical literature, but, as might have been expected, he deprecated overmuch writing. When one comes to appraise his work it is difficult to decide where to lay the greatest emphasis—on the surgeon, the teacher, or the man. He was a great surgeon, and, as a pupil of great surgeons, carried on their work with a skill and quality which was no less than theirs. Indeed, as an all-round surgeon he was

probably unexcelled. As a diagnostician he was eminently sound, and he was never to be cajoled into operating if he did not feel that it was the only justifiable course. Usually he was right. His teaching influence probably found its greatest response among the junior surgeons of the Leeds school, all of whom would bear testimony to the value of his influence—in technical dexterity, in inspiration for research, and in surgical honesty. Honesty, indeed, was the outstanding quality of the man, combined with a fearless courage. This sometimes led to misunderstanding by those who did not know him well enough to see beyond an outspokenness, a brusqueness of manner, that were the defects—if defects they were—of his qualities. Vision, combined with unswerving rectitude, was the keynote of his practice, his teaching, and the man himself. It kept him in the van of progress; it compelled universal trust and confidence, and leaves colleagues and friends to mourn the loss of "Joe," as he was affectionately called by most of those with whom he worked. Behind his forcefulness lay a simple and most kindly disposition, as those who sought him in trouble learned to know so well.

He was chairman of the Faculty of the Leeds General Infirmary for some years, and his constructive and administrative work for that institution was of the greatest value, though not always finding immediate acceptance. His contribution to this service of the hospital has been much missed, even during this last year of illness. He was elected chairman of the Leeds Division of the British Medical Association in 1931, and in the same year was a vice-president of the Section of Surgery at the Eastbourne Annual Meeting.

He was a keen fisherman, and loved his gun. He was a Freemason of standing in the craft, having been W.M. of Zetland Lodge. His great sorrow was the loss of an only daughter in her school days. He leaves a widow.

[The photograph reproduced is by Brittenden, Leeds.]

PHILIP G. LEE, L.R.C.P. and S.I.

Surgeon, Victoria Hospital, Cork

Dr. Philip G. Lee died recently at his residence, 10, Patrick's Hill, Cork, after an illness which lasted over two months. He was a member of a very old Cork family which had many connexions with the Church; his grandfather, the Rev. Giles Lee, was principal of the old Diocesan School, Patrick's Hill. Dr. Lee was a student of Queen's College, Cork, when it was a constituent college of the late Queen's University and the Royal University, Ireland. He became a licentiate of the Royal Colleges of Surgeons and Physicians in 1888. For many years he was surgeon at the Victoria Hospital, Cork; previously he was clinical assistant at the Cork Eye, Ear, and Throat Hospital, visiting physician to the Cork Maternity Hospital, and physician to the Cork Sailors' Home and Lapps' Charity. He was a member of the Irish Committee of the British Medical Association, and from 1903 to 1923 was honorary secretary of the Munster Branch. In 1927, when Dr. Alfred Cox made a tour of the Branches in Ireland, Dr. Lee contributed to the success and pleasure of his visit, and among the many places of historical and antiquarian interest which Dr. Cox visited with him was Blarney Castle. Dr. Lee was a highly cultured man, and although he had a large practice he devoted considerable time to local historical and antiquarian research. He was one of the first members of the Cork Historical and Archaeological Society, and for several years was honorary secretary and editor of its journal. He was also a member of the Royal Irish Academy and a Fellow of the Royal Society of Antiquaries of Ireland. By the death of Dr. Lee the profession in

Ireland has lost a loyal member, whose character and standard of conduct were an example to the younger generation of medical men. His widow and family have the deepest sympathy of the profession in their bereavement.

We regret to announce the death, on February 8th, at the age of 81, of Dr. WALTER MERCER of Barnet, who had practised in the district for fifty years. After graduating M.B., C.M. at Edinburgh in 1881, he had further hospital experience in Vienna. He had been a member of the British Medical Association since 1890. He first went to Barnet in 1883 as an assistant to Dr. Charles Carter, was later taken into partnership, and shortly afterwards succeeded to the practice. A man of wide sympathies and of charming personality, Dr. Mercer was looked upon as a friend by all his patients. Always keenly interested in education, he was largely instrumental in bringing about the establishment, in 1889, of the Hyde Institute, of which he was chairman of the trustees, and which, through his co-operation and advice, was amalgamated a few years ago with the Barnet branch of the county library scheme. At the time of his death Dr. Mercer was chairman of the Library Committee. He was consulting surgeon to the Barnet Victoria Cottage Hospital, and to the Pawling Home-Hospital for Children at Hadley. When a young man he was well known as an Alpine climber, his holidays in Switzerland being spent in that way, or else in walking in the North of England. The funeral took place at Monken Hadley Church on February 12th.

It is with regret that we announce the sudden death, on February 13th, of Mr. ALBERT EDWARD TUNSTALL of Thornton, Bradford. He was working in his surgery when he had a sudden and unexpected attack of cardiac failure, which proved fatal in a few minutes. He received his medical education in Glasgow, and qualified L.R.C.P., L.R.C.S.Ed., L.F.P.S.Glas. in 1885. After acting for a period as an assistant he settled in practice in Thornton, Bradford, and for over forty years carried on a busy general practice there. He was at one time medical officer of health for Thornton, Clayton, and Denholme urban district councils. In recent years the two former areas were absorbed into Bradford, but he still held the post at Denholme at the time of his death. During the Great War he was on the emergency staff of the Bradford War Hospital and did valuable work there. He was always a very keen member of the British Medical Association, and was chairman of the Bradford Division during the period of the war; he also acted as one of the Representatives of the same Division at the Annual Representative Meeting for twelve years. He was for some years a member of the Local Medical and Panel Committee. Tunstall was universally loved, both by his patients and by his professional brethren. He was a very reliable man, with a genial smile, and possessed common sense and sound judgement. He will be greatly missed by all those who knew him, and also by Thornton Parish Church, of which he was a very active member. He leaves a widow, one son, and three daughters.

The following well-known foreign medical men have recently died: Dr. PIERRE BAZY, surgeon to the Paris hospitals, member of the Académie de Médecine and Académie des Sciences, and Commander of the Legion of Honour; Professor F. C. C. HENSEN, the eminent anatomist and palaeontologist of Copenhagen, aged 63; Professor RICHARD KÖCKEL, director of the Institute for Forensic Medicine at Leipzig, aged 69; Dr. LEROY CRUMMER, clinical professor of medical history and bibliography, University of California Medical School, and author of *Clinical Features of Heart Disease*, aged 61; Dr. HENRYK HALBAN, professor of neurology and psychiatry, and rector of the University of Lwow, Poland, aged 63; and Professor ARTHUR ROUSSEAU, dean of the medical faculty of Quebec, and corresponding member of the Académie de Médecine.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The House of Commons this week resumed the committee stage of the Unemployment Bill. This was amended to exempt the first 20s. of an ex-service man's wound or disability pension for the calculation of means, and in other ways. Debate also arose on the Russian Trade Agreement.

The House of Lords passed the Contraceptives Bill through committee.

The Birmingham United Hospitals Bill and the Bill relating to the South Devon and East Cornwall Hospital, the Plymouth Royal Albert Hospital, and the Devonport and Central Hospital, Plymouth, both await second reading in the House of Lords. The Standing Orders have been complied with in each case.

The North Buckinghamshire Joint Hospital District Bill was read a second time by the House of Lords on February 21st. The Wirral Joint Hospital District Bill passed the report stage in the House of Commons on February 22nd, and was read a third time and passed by the Commons on February 23rd.

The Diseases of Fish Bill was read a second time in the House of Lords on February 21st. Earl De La Warr explained that it dealt with furunculosis, a disease which first occurred among trout in England about 1907. It had occurred later among salmon in many Scottish and some English and Welsh rivers. The Bill was based on the recommendations of a committee set up in 1923 under Professor Mackie of Edinburgh. It took powers to prohibit the importation of live salmon and trout into Great Britain. The disease was endemic in many of the fish farms on the Continent. Live eggs and other live freshwater fish would be admitted under licence. The Bill also gave power to take samples of live fish and order the destruction of infected stocks. The powers could be extended by Order in Council to any other infectious diseases of fish which might damage the inland fisheries of Great Britain.

A Vote on Account issued as a Parliamentary paper on February 23rd shows that the total Estimate for the Ministry of Health in the year 1934-5 is £19,639,924. For the Board of Control the Estimate is £140,747, for the Scottish Department of Health £2,982,420, and for the Scottish Board of Control £16,177. For Universities and Colleges in Great Britain the vote is £1,920,000. These Estimates differ little from the net adjusted Estimates for 1933-4 in the same Departments. The Ministry of Health, Scottish Department of Health, and grants for Universities and Colleges show respectively increases approximating to £439,500, £150,200, and £30,000.

On February 26th Sir SAMUEL HOARE presented the Indian Pay (Temporary Abatements) Bill, which extends the period in respect of which abatements from pay may be made under the Indian Pay (Temporary Abatements) Act, 1931.

On February 26th Sir ROBERT GOWER presented the Coal Mines (Protection of Animals) Bill, which proposes to amend the provisions of the Coal Mines Act, 1911, relating to the care and protection of horses and other animals used in mines.

In the House of Lords, on February 27th, the Ministry of Health Provisional Order Wirral Joint Hospital District Bill was read a first time.

In the House of Lords, on February 27th, the Diseases of Fish Bill passed through committee, with amendments.

A meeting of the Parliamentary Medical Committee has been arranged for March 7th in order that Lord Moyrihan shall speak on road accidents and Lord Dawson on the Contraceptives Bill.

Contraceptives Bill in Committee

In the House of Lords, on February 27th, the Contraceptives Bill was considered in committee. On Clause 1 (restriction of sale, display, and advertisement of contraceptives), Lord DAWSON OF PENN moved an amendment lifting the restriction on the display of contraceptives in, on, or outside any shop. He said contraceptives themselves were extremely dull-looking things, and would not attract the attention of anybody. It was always undesirable to restrict, unless there was a good case for restricting, and he did not think the case for restriction here was adequate. It had, further, been pointed out to him that in the less populous districts many married women were shy of asking for contraceptives, but that if the articles were shown in the windows of shops they would go in and ask for "what was in the window." He wished to make it clear, as introducer of the Bill, that though the chief object was to protect immature youth by doing away with obtrusive sale and display, he was equally anxious to do nothing which would put any unreasonable, or, indeed, increased resistance in the way of contraceptives being made available to all sections of the married population.

Lord SNELL said there were possibilities of chemists engaged in legitimate business being harried by prosecution in borderline cases. There were instruments on sale in chemists' shops which were, in their nature, of a sanitary and necessary character, and which might also be contraceptives. The clause seemed ill defined, even with the amendment. Lord DAWSON, replying, said he had made it his business to find out the views of the pharmaceutical chemists. They were a very well organized body, and within the last six months they had had conferred on them powers which enabled them to take disciplinary action with regard to their members. The chemists' shops were well controlled now, and would be under still better control in future. He had had it from the organization of the pharmaceutical chemists that there was nothing in this amendment, or the others following it, of which they disapproved. It was the pictures and written descriptions which had a bad influence. The clause, as amended, would permit of nothing more than a label or simple notice.

The amendment was carried by 38 votes to 20.

Lord Dawson moved an amendment bringing illuminated signs advertising contraceptives under the restrictions of the paragraph, and this was agreed to. At a later stage he moved to add to paragraph (d) the following:

"Provided that nothing in the foregoing provisions shall render unlawful (i) the sale or offer for sale of any contraceptive by a qualified medical practitioner, registered nurse, or certified midwife, to a person or to the husband or wife of a person whom the practitioner, nurse, or midwife is attending professionally; (ii) the sending or delivery to any person of any book, newspaper, or magazine containing advertisements of contraceptives, unless the book, newspaper, or magazine is published wholly or mainly for the purpose of advertising contraceptives."

This amendment also was agreed to.

The EARL OF IDDESLEIGH moved an amendment to increase the age from 18 to 21 years of any unmarried person in regard to whom it would be an offence to send or deliver any circular, advertisement, or any other document (for the purpose of any trade or business) containing information relating to contraceptives. The EARL OF FEVERSHAM, on behalf of the Home Office, said it would not make much difference in the administration of the law whether the age was 18 or 21. Lord Dawson said that when he was trying to frame the Bill he found more difficulty over this subsection than any other. Masses of the people matured more quickly than in former days, and married early. One did not wish to keep propaganda from a youth or girl engaged to be married and wanting to marry. If anybody wished to put the age at 19, he did not mind, but he was sure that 21 would be wrong. The result would be to drive the whole thing underground, which they wanted to avoid.

The amendment was negatived.

Lord MERRIVALE moved a new clause making the supply of contraceptives to an unmarried person under 21 a misdemeanour punishable by fine or imprisonment. Lord BANNURRY asked how a shopkeeper was to know whether a young woman was married or what her age was. Lord Dawson said that he thought Lord Merrivale would defeat

his object by the amendment. They wanted on the one hand to remove the slur from contraception and get it into right channels, and on the other hand to prevent what was illicit. Some of these contraceptives were used not only for the control of conception but for the prevention of venereal disease. Did they want an increase in the illegitimate birth rate? They would certainly get it if this clause were inserted. No ecclesiastical authority had ever succeeded in crushing out contraception, and in this particular age they were less likely to be successful than before.

Lord MERRIVALE withdrew his amendment.

On Clause 2 (Interpretation) Lord DAWSON moved two amendments to strengthen the definition of contraceptives in order to prevent their being sold under a guise. As amended the definition read: "Any appliance, instrument, drug, preparation, or thing, designed, prepared, or intended to prevent pregnancy resulting from sexual intercourse between human beings." The amendment was agreed to.

The EARL OF IDDESLEIGH moved an amendment to include among the meanings of a "public place" any garage and licensed premises to which the public have or are permitted to have access. Lord Dawson accepted the amendment, which was altered to read: "a public garage and licensed premises," and it was agreed to. A further amendment by Lord BERTIE to insert among the "public places" a "place of entertainment" was agreed to.

The Bill as amended passed through committee and was reported to the House.

Osteopaths Bill

In the House of Commons, on February 21st, Mr. BOOTHBY asked leave to bring in the Registration and Regulation of Osteopaths Bill—"to regulate the practice of osteopathy and to prescribe the qualifications of osteopathic practitioners." He said the Bill was to set up a statutory board with the necessary powers and authority to compile a register of qualified osteopaths, and to provide for the admission to that register of persons who followed a prescribed course of study and acquired a prescribed standard of professional competence. It would give the qualified osteopath the right to employ a qualified anaesthetist without the latter falling under the ban of the General Medical Council. Under this Bill osteopaths did not seek inclusion in the medical profession. Many diseases had their origin in maladjustments of the framework of the body, and cures for those diseases could be effected by the skilled osteopath through manipulative therapeutics, which released certain natural forces in the body. These forces, without the aid of drugs or of surgery, brought about cures. He believed its failures to be due to quacks practising osteopathy under no form of regulation. The Bill was to eliminate these quacks. Osteopaths asked to be recognized for their own regulation and for the protection of the British public. The practice of osteopathy in this country had now reached such dimensions that the House of Commons ought either to prohibit it or to allow osteopaths to submit themselves to proper regulation in the interests of the public.

The Bill was read a first time without opposition, and the text has since been issued. It is identical with that of the Bill introduced in 1933.

Purer Milk Supply: A Government Policy

Replying to Mr. Lambert, on February 22nd, Dr. ELLIOT said that the Government would be prepared to contribute from the Exchequer on a pound for pound basis to a milk publicity fund for a period of two years, up to a limit of £500,000 in either year, according to the amount contributed by the Milk Marketing Boards. The grant would be contingent on the submission of an approved programme containing provision for the supply of milk to schools at reduced rates. Milk surplus to present liquid requirements was estimated to be little short of 20 per cent. of the total volume of milk sold by contract this winter, and was likely to be about 40 per cent. in the spring and summer. An expansion of the liquid milk consumption would be of the greatest benefit from the public health point of view and would alleviate the difficulty of "surplus milk." This increase in consumption must be based on public confidence

as to the security of the supply. To launch a campaign to secure a purer milk supply the Government would provide a sum not exceeding £750,000, spread over the next four years. The requisite legislation would be introduced at an early date. Dr. Elliot said it was common knowledge that the purity of the milk supply in the United Kingdom was not so great as all would desire. The £750,000 was to be devoted entirely to cleaning up the herds and securing a pure milk supply.

Durham University Royal Commission

Mr. CHAMBERLAIN announced, on February 22nd, that Lord Moyne had consented to be chairman of the Royal Commission to inquire into the organization of the University of Durham and its constituent colleges. He hoped soon to announce the names of the other Commissioners.

Water Supplies and the Drought

The second reading of the Rural Water Supplies Bill was moved in the House of Commons on February 22nd by Sir HILTON YOUNG, who said that the drought of 1933 was not so bad as that of 1921, but it had gone on longer. In the towns water reserves were half what they would normally be in February, but there had been no exceptional difficulty in getting regular supplies, and the position was secure for the immediate future. If there was a good rainfall during March the situation would be secure, apart from minor inconveniences. If not, the authorities must prepare for exceptional measures, such as the reduction of compensation water, the removal of restrictions on the amount of water taken from various sources, the emergency development of new sources, the restriction of the use of water, and measures to enable one authority to get water when another authority had a surplus. He had addressed a circular to all water undertakings enjoining immediate adoption of such emergency measures where necessary. The position of the rural authorities was more anxious and difficult. The most important measure which could be taken in rural areas was purification of supplies otherwise not available because they were impure. The modern process of purification was easily applied, and required little technical knowledge. By it a stream or a well hitherto not quite safe for use could be available in an emergency with safety to the public health. The last resort in rural areas was organized house-to-house distribution. He was asking all the rural district councils to report what emergency measures they had taken to relieve water shortage, and what further action could be taken. The engineering inspectors of the Ministry of Health would help rural areas to create emergency measures, and, if necessary, the expert staff of the Ministry would be increased. The Bill proposed to aid permanent measures for improving water supplies in rural areas. In some places supplies could be made available by tapping or linking up with neighbouring supplies. Practical men did not accept the idea of the distribution of water all over the country from central sources of supply. Water could often be got locally by driving a bore hole and by small expenditure on a reservoir and a pump. For encouraging such and similar rural works the Bill would provide the Ministry of Health with £1,000,000.

Mr. GREENWOOD moved the rejection of the Bill in a reasoned amendment, which called for a national co-ordinated scheme. He said the London area was never going to lack water because its supplies were in a local "grid," the area was large and was governed by an executive authority—the Metropolitan Water Board. Sir Hilton Young should sweep away all the obsolete Acts about compensation water, and give the regional water committees complete and final power. Sheffield had been able, in 1929, to provide Barnsley with 2,000,000 gallons a day, but it had to give away 5,000,000 gallons a day in compensation water. Mr. TURTON said that land drainage, water supply, and sewerage schemes should go together. To initiate a water supply scheme in an area with a faulty sewerage system was to risk a tragedy such as that associated two years ago with Malton. Sir HENRY CAUTLEY agreed that when a water supply was brought into a village a sewerage scheme must be provided within a year or two years. Consumption of water rose from two or three

gallons to twenty or twenty-five gallons, the cesspools were inadequate, and the village was likely to be attacked by disease. Mr. CHORLTON said the Minister had not taken account of the great increase in consumption. In Scotland some towns used over 100 gallons per head per day. In England the amount was considerably less. The Metropolitan Water Board supplied about thirty gallons per day. To remove the limitations on the amount of water taken from rivers would require legislation. Improvement of water supply was one of the best ways of improving milk supplies. Sir ARCHIBALD SINCLAIR said that in areas of the Highlands and other rural districts of Scotland ordinary supplies were inferior and became dangerously bad in an emergency like last summer. Lord SCONE spoke of the great and increasing strain thrown on rural water supplies by the provision of houses fitted with modern conveniences and by the conversion of older houses. Mr. SKELTON announced that in Scotland where assistance was needed in an area which was not a special water district such a district would be formed. Mr. EASTWOOD refuted allegations of a dangerous shortage in Kettering, and said that that town had supplies for eight or ten weeks.

Mr. SHAKESPEARE, replying to the debate, said that the Minister, in estimating the burden on a locality and its ability to pay for a water supply, would take into account the extra burden caused by the sewerage scheme necessitated by a water scheme. Of 102 large water undertakings, eighty-seven reported that "the supply was satisfactory." Glossop, Buxton, and Stowmarket denied press reports of acute shortages.

The Bill was read a second time by 188 to 36.

Sir HILTON YOUNG told Sir Gifford Fox, on February 22nd, that he had been informed of shortage of water supplies due to drought in parts of the rural districts of Banbury, Bullingdon, Chipping Norton, and Witney. Schemes for the permanent improvement of the water supplies in these areas were under the consideration of the four councils. A scheme for four parishes in the Ploughley Rural District had been approved.

Stone and Coal Dust in Mines.—Mr. ERNEST BROWN stated, on February 21st, that the measures taken to prevent the use on underground roadways in collieries of stone dust, which would be injurious to health, were based on the character of the dust itself rather than of the mixed dusts on the roadways. In 1932, 3,864 samples of dust on underground roadways were taken by colliery inspectors, and 87 per cent. proved to contain 50 per cent. or more of incombustible matter. The amount of coal dust necessary to propagate an explosion in a mine varied. The finest dusts of the most inflammable coals were the most explosive. The least quantity that would propagate a flame was less than one-tenth of an ounce per cubic foot of air. Explosions had been produced experimentally with as much as two ounces of such coal dust per cubic foot of air.

Housing.—Replying to Mr. Stourton, on February 22nd, Sir HILTON YOUNG said that it had never been possible to arrive at a trustworthy arithmetical estimate of the number of Class C houses required in urban and rural areas in order to provide every working-class family with reasonable housing accommodation, though some information of the kind was contained in the census forms. Replying to Mr. Levy, he said he was unaware that any of these houses were being built without provision for water supply and without adequate sanitary arrangements.

Police Surgeon's Examination of Accused Man.—Sir JOHN GILMOUR told Mr. Isaac Foot, on February 22nd, that he had seen press reports of the remarks of Mr. Justice Swift at the Liverpool Assizes, when, upon the trial of a man charged with manslaughter, who was alleged to have been under the influence of drink and unfit to drive a car, the judge questioned the right of the police to call in the police surgeon to examine the accused man. He could not say what action, if any, would be called for on his part until he had ascertained the precise circumstances and considered them carefully.

Notes in Brief

At Broadmoor Criminal Lunatic Asylum are 204 patients who have been detained there more than twenty years.

Medical News

The following special discussions have been arranged at the Royal Society of Medicine (1, Wimpole Street, W.): On Wednesday, March 7th, at 8.30 p.m., on *baematemesis*, by a joint meeting of the Sections of Surgery and Medicine; and on Thursday, March 15th, at 8.30 p.m., by the Sections of Neurology and Disease in Children, on the nervous complications of the acute fevers and exanthemata.

The twenty-fourth annual general meeting of the Ladies' Guild of the Royal Medical Benevolent Fund will be held at British Medical Association House, Tavistock Square, W.C., on Wednesday, March 7th, at 3 p.m., with Lady Cheatle in the chair. Speaker, Dame Madge Kendal, followed by a reception.

The annual meeting of members of the Cremation Society will be held at 23, Nottingham Place, W., on Thursday, March 8th, at 3.30 p.m.

An address entitled "Science, Philosophy, and Religion" will be given before the British Institute of Philosophy by the Dean of St. Paul's, at University College, Gower Street, W.C., on Tuesday, March 13th, at 8.15 p.m. Cards of admission can be obtained from the Director of Studies, at University Hall, 14, Gordon Square, W.C.1.

A lecture on the theory and practice of contraception will be given to medical students on Tuesday, March 13th, at 6 p.m., at the Walworth Women's Welfare Centre, 153A, East Street, S.E.17. Practical demonstrations will be given at 6 and 7 p.m. on March 20th and 27th. Students attending a demonstration are requested to bring rubber gloves with them. The lectures are open to all those who have completed their gynaecological course. Tickets (2s. 6d.) admitting to the lecture are to be applied for in advance.

Part II of the series of lectures and practical courses of instruction for the diploma in psychological medicine at the Maudsley Hospital commenced on February 26th and will be continued during March, April, and May. The fee for the whole of Part II is £10 10s. Inquiries as to lectures, fees, etc., should be addressed to Dr. F. Golla, honorary director of the medical school, Maudsley Hospital, Denmark Hill, S.E.5.

The Fellowship of Medicine and Post-Graduate Medical Association (1, Wimpole Street, W.) announces that the eighth lecture-demonstration on anaemia, by Dr. Clark-Kennedy, at 11, Chandos Street, W., will be given on March 6th, at 2.30 p.m. The subject on March 13th will be iron and liver. A week-end course on clinical surgery will be given at the Royal Albert Dock Hospital on March 10th and 11th, occupying the whole of each day. A demonstration of neurological cases will be given by Dr. L. R. Yealland, at the National Temperance Hospital, Hampstead Road, on March 10th, at 3 p.m., and a whole-day course in orthopaedics, at the Royal National Orthopaedic Hospital, from March 12th to 24th. Other forthcoming courses include a week-end course in chest diseases at the Brompton Hospital, March 24th and 25th; infants' diseases at the Infants Hospital, April 9th to 21st; proctology at St. Mark's Hospital, April 9th to 14th; rheumatism at the British Red Cross Clinic, on Tuesday and Thursday evenings, April 10th to 26th. Detailed syllabuses of all courses may be obtained from the Fellowship.

The fifty-eighth congress of the German Society of Surgery will be held at the Langenbeck-Virchow House, Berlin, from April 4th to 7th, under the presidency of Kischner of Tübingen, when the subjects for discussion will be the treatment of pyogenic infections and their sequelae, introduced by Lexer, and the surgery of gastrointestinal cancer, introduced by Goetze.

The seventh congress of the German Society for Investigation of the Circulation will be held at Bad Kissingen on April 16th and 17th, when the subject for discussion will be thrombosis and embolism, introduced by Geh. Rat Professors L. Aschoff of Freiburg, P. Morawitz of

Leipzig, and L. Nurnberger of Halle. Further information can be obtained from the secretary, Professor E. Koch, Bad Nauheim.

The second conference of the Alliance Scientifique et Médicale Française was held at Bordeaux on February 3rd, and illustrated the closeness of the relation between medicine and biology. After showing some films, including two illustrating the laws of reflexes and the clinical evolution and treatment of syphilis, Dr. Clauoué urged the importance of attention being devoted to hospital accountancy in connexion with public assistance cases more particularly. The next conference has been fixed for April 7th at Bordeaux. Further information may be obtained from Dr. Clauoué, 39, rue Scheffer, Paris, XVIc.

The Royal Society of Medicine announces that the tenure of the William Gibson Research Scholarship has been extended to Dr. Audrey E. Russell, the present holder, for the third year; and that the fourth award of the Nichols Prize has been divided equally between the essays submitted by Dr. J. Smith of Aberdeen and Dr. Ronald Hare of Queen Charlotte's Maternity Hospital, London.

About 150 medical graduates accepted invitations from the University of London Medical Graduates Society for the At Home held at B.M.A. House, Tavistock Square, by courtesy of the British Medical Association. After tea the company was greatly entertained by the interesting film on antimalarial work in the Empire, demonstrated by Major Lockwood Stevens; thereafter parties were conducted over the building and found great interest, especially in the setting up of the *British Medical Journal*. Particulars as to membership of the society can be obtained from the honorary secretaries, 11, Chandos Street, W.1.

Geh. Med.-Rat Professor M. Borst has been nominated president of the German Committee of the Campaign against Cancer.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, *British Medical Journal*, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE *BRITISH MEDICAL JOURNAL*, *Aitiology* Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate* Westcent, London.

MEDICAL SECRETARY, *Mediscra* Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumshagh Gardens, Edinburgh (telegrams: *Assoc. etc, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Treatment of Actinomycosis

Dr. P. B. PINKERTON (West Kirby, Cheshire) writes: I would be grateful for any information regarding any new developments in the treatment of actinomycosis. I have a severe case at present which is not going well. Deep x-ray therapy, iodine (Lugol's solution) by the mouth, and iodine intravenously have not proved of much benefit. Is there any truth in the statement, which I heard from French sources, that there are cases in which iodine is definitely harmful?

Chronic Gonococcal Infection

Dr. J. SANDISON CRABBE (Birmingham) writes in answer to "Perplexed": This is no doubt a case of chronic prostatic infection. I have cleared up more than a dozen cases with diathermy to the prostate, after Cumberbatch's method. Some of these have been of fifteen years' standing. "Perplexed" should read Cumberbatch and Robinson's book *Treatment of Gonococcal Infection by Diathermy*.

Pruritus Ani

"M. O." writes: The discussion in your columns prompts me to call attention to the fact that many people suffer from a minor form of this complaint, which is undoubtedly due to an incorrect diet, disappears on correction of this, and reappears on resumption of the causative foods. The latter is especially prone to occur during a temporary absence from home. I have not been able to satisfy myself fully whether this is merely an avoidance of a constipating diet or whether there is some other factor—for example, the relative acidity or alkalinity of the faeces or some change in their bacterial composition dependent on the diet. I strongly suspect that it is not merely a matter of constipation, but would like enlightenment on this point if any of your readers are in a position to give it. In my personal experience bread, and especially new bread, is the most potent cause of pruritus of this kind, and I have found that the substitution of potatoes and the inclusion of fresh fruit and vegetables brings about a complete disappearance of the discomfort. An excess of meat also seems to produce pruritus, but not to the same extent as bread and puddings, etc., made of flour. The substitution of wholemeal bread does not, I think, make any difference.

Calot's Solution Formula

"S. A. D. M." writes with reference to "G. B.'s" inquiry: The solution consists of the following: guaiacol, 1 gram; creosote, 5 grams; ether, 30 c.cm.; iodoform, 10 grams; olive oil, 70 c.cm. This formula is that published in the *Medical Journal and Record* (October 4th, 1933). Instructions should be given to the chemist that before adding ether the mixture should be gradually heated in olive oil until the iodoform is completely dissolved and the mixture clear. This is the same as in Martindale's *Extra Pharmacopoeia*, except that in it liquid paraffin is used instead of olive oil; most might prefer to use the former.

Income Tax**Deduction for Rental Value**

"J. L." inquires what small book can be recommended dealing with income tax, and what he should deduct for rental value of the house he owns.

** A useful little book is *Income Tax and the Professional Man*, published at 4s. 6d. by Crosby, Lockwood and Son, Stationer's Hall Court, Ludgate Hill, E.C.4. It is difficult to advise on the proportion of rent, or rental value, which should be deducted as a professional expense; so much depends on the ratio of professional to private use. As a rough guide we may perhaps say that where there are a waiting and a consulting room on the ground floor, and a garage used mainly for professional purposes, a common allowance would be one-half; where the professional use is less than normal possibly one-third would be fair. Deductions for rates (and, frequently, lighting and heating costs) would follow the same ratio.

Motor Expenses: Surgery away from Residence

"ROSARINA" uses a car (a) for travelling to his surgery—about a mile from his residence, (b) visiting hospitals as a visiting surgeon, and (c) to a slight extent for visiting patients. Do these count as professional purposes, and should he claim the depreciation allowance?

** Items (b) and (c) are undoubtedly "professional"; (a) is open to argument, and in strictness may be disallowable, but the authorities seldom seem to object where there is a reasonable amount of clear professional use. Depreciation should be claimed, and when the car is renewed a claim for "obsolescence" allowance should be made—that is, for the deduction of the loss on sale less the amount of depreciation allowance received.

New Proprietorship—Cash Basis

"S. W." took over his present practice on January 1st, 1933, but took over no book debts. On a cash basis—which was accepted for his previous practice—his profits for 1933 would be £470, but he is told that "for the first three years he must pay tax on every book debt at full value." The 1933 profits on that basis amount to £798.

** Tax is payable on profits whether they have been received in cash or are still outstanding as debts. "S. W." however, is entitled to value those debts individually, and can claim to deduct, as a "bad debts reserve," the excess of the nominal or gross amount of the debts over their fair value. This applies for three years, after which the Revenue authorities are usually prepared to assume that the cash receipts of the year will approximate close enough to the value of the year's bookings to serve as a reliable index of the gross income of the practice. It is presumed that he is not paying tax on delayed receipts from his former practice.

LETTERS, NOTES, ETC.**Greenstick Fracture in a Male aged 21**

Dr. R. SALISBURY WOODS, F.R.C.S. (Cambridge), writes: I think this case may be of some interest, and I should be glad to hear whether many of your readers have seen similar fractures in an adult. An undergraduate aged 21½ years fell heavily on the point of his right shoulder in tackling another man, who fell on top of him. There was an audible "crack" and he experienced severe pain in the region of the clavicle and went off the field. I saw him that evening, when the clavicle presented an exaggerated bowing and extreme tenderness about the middle, but no swelling of the soft parts. It seemed to me that he must have a greenstick fracture, but I must confess that when I sent him for x-ray examination I felt that my diagnosis might be corrected. However, the skiagram confirmed the diagnosis, there being a definite split in the upper surface, and no solution of continuity of the lower.

British Industries House

The proposal to establish a permanent medical exhibition at British Industries House, Marble Arch, W., referred to on February 17th (p. 294), has met with generous support from manufacturers throughout the kingdom. The whole of the third floor, comprising some 9,000 square feet, has been allocated to the medical section, and this space has been arranged to accommodate 150 exhibitors. Up to the present time inquiries from British manufacturers regarding the allocation of space have been received from eighty-four different firms. We are informed by the chairman of the Advisory Council, Dr. Alfred Cox, that the eighty-four firms comprise: manufacturing chemists, 21; dental, 5; hospital equipment, 7; medico-electric, 3; medicinal foods, 5; opticians, 12; surgical appliances, 9; surgical dressings, 3; surgical instruments, 6; toilet requisites, 4; x-ray apparatus, 2; printers and publishers, 7. The club premises will soon be open, and will be available for the use of visitors in advance of the formal opening of British Industries House. Any doctor, on presentation of his card, will have free access, both to the section and to the club, and the same facilities apply to authorized representatives of nursing homes and similar institutions in this country and over-seas.

Broadcasting and Contraceptives

Dr. H. D. BISNOR (medical officer of health for Guernsey) writes under date February 19th: The B.B.C. last week broadcast a résumé of the discussion upon the Bill which Lord Dawson sponsored in the House of Lords, for regulating the sale of contraceptives. This broadcast must have been heard by many thousands of children and adolescents, whose natural curiosity was aroused, and who asked their grown-ups what contraceptives were. Unfortunately nowadays the days of innocence are short enough, and although agreeing that mere ignorance is not always innocence, even the most cynical of us must desire that children should be protected from a premature knowledge of sexual matters until it is necessary that they should be enlightened upon them. I cannot believe that such a broadcast would not be severely condemned by an overwhelming majority of the members of the British Medical Association, and if I be so I venture to hope that its leaders may see fit to inform the B.B.C. that in such matters we have the right to expect something better from it.

Vacancies

Notifications of offices vacant in universities, medical colleges and of vacant resident and other appointments at hospitals will be found at pages 49, 50, 51, 52, 53, and 56 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 54 and 55.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 84.

THE USES AND DANGERS OF HYPNOTIC DRUGS OTHER THAN ALKALOIDS

BY

SIR WILLIAM WILLCOX, K.C.I.E., C.B., C.M.G., M.D., F.R.C.P.

PHYSICIAN TO ST. MARY'S HOSPITAL

In July, 1913, I had the privilege of opening a discussion at the Annual Meeting of the British Medical Association at Brighton, in the Section of 'Pharmacology and Therapeutics,' on "The Use and Abuse of Hypnotics." Sir Maurice Craig participated with me on that occasion, dealing with the subject from the aspect of psychiatry. It is appropriate that on the present occasion the same subject should be discussed by the Royal Society of Medicine by the Section of Therapeutics and Pharmacology and the Section of Psychiatry at a joint discussion.

Since 1913 the chief advances in our knowledge of hypnotic drugs have been: (1) the discovery and addition to the list of hypnotic drugs of very many new derivatives of the barbituric acid series; (2) the introduction of a number of drugs other than alkaloids for purposes of basal anaesthesia.

A hypnotic drug may be defined as a drug or combination of drugs which produce sleep resembling natural sleep. Insomnia is due to many causes, such as pain; nervous causes, such as psychical disturbances and organic diseases of the nervous system; toxic causes, such as microbial infections, auto-intoxication, drug addiction, and chemical poisons; disorders or diseases of the various systems, such as gastro-intestinal, cardiovascular, respiratory, genito-urinary, or endocrine systems.

In the treatment of insomnia the first step is to elucidate its cause, and it will be generally agreed that the use of hypnotic drugs should be resorted to only when other general methods of treatment have failed to bring about a satisfactory result or are likely to be of inadequate effect. The choice of the hypnotic for a particular case will largely depend on the cause of the insomnia—for example, after a severe abdominal operation one would probably select a drug not belonging to this series at all (such as a hypodermic injection of morphine) in order to induce sleep on the night after the operation. Drugs of vegetable origin will be excluded from consideration.

CLASSIFICATION OF HYPNOTICS

The classification of hypnotic drugs on a purely chemical or pharmacological basis is difficult and unsatisfactory, so that an attempt will be made to classify them on chemical and clinical lines.

Hypnotic drugs of low toxicity are: the inorganic bromides (for example, potassium, sodium, ammonium, calcium, and strontium)—they are mild hypnotics suitable for certain nervous cases, and may be given in full doses up to 30 grains at night; alcohol in certain cases in prescribed amount; phenazone and its derivatives, such as pyrantidon; aceto-salicylic acid, and salicylate derivatives; phenacetin, etc. Combinations of these with other hypnotics, such as opium preparations or codeine, are often effective.

A number of hypnotic drugs of varying degree of toxicity belong to the alcohol-chloral group.

THE ALCOHOL-CHLORAL GROUP

Chloral (dose 10 to 20 grains) is an effective, rapidly acting, and safe hypnotic. In full doses it is depressant to the heart and respiratory functions. If used continuously it may have a toxic action on the liver and

cause toxic jaundice; also it may give rise to addiction. This hypnotic has undeservedly fallen into disuse.

Chloralamide (chloral formidum, B.P.—dose 15 to 45 grains) is a safe and mild hypnotic. Like chloral, it is incompatible with alkalis, which cause decomposition. When used on successive nights the hypnotic effect is apt to diminish, so that this drug is used much less than formerly.

Other chloral derivatives not commonly used at the present time are: Butyl chloral (dose 5 to 20 grains), useful in the insomnia of neuralgia. Chloralose (dose 3 to 10 grains), a compound of chloral and glucose; it is not free from toxic effects such as excitement, tremors, and cardiac depression, and is rarely used. Chlorbutol, also known as "chloretone" (dose 5 to 20 grains); more toxic and less effective as a hypnotic than chloral. Hypnal, a compound of chloral and antipyrine (dose 5 to 15 grains), is rarely used. Dormiol, a compound of chloral and amylene hydrate (dose 5 to 40 minims), is rarely used. Ural, a compound of chloral and urethane (dose 15 to 45 grains), a dangerous and uncertain hypnotic. Isopral is trichlor-isopropyl alcohol (dose 10 to 30 grains); it has fallen into disuse owing to its toxic effects in causing cardiac depression and gastric disturbance. Bromal (dose 2 to 5 grains) is more toxic and less certain in hypnotic action than chloral.

Paraldehyde (dose 1/2 to 2 drachms) is a useful and safe hypnotic, with an unpleasant taste; soluble in water 1 in 9; it is contraindicated in gastric and respiratory diseases; its repeated use may cause toxic liver effects and give rise to addiction. Amylene hydrate (dose 30 to 60 minims) acts like paraldehyde, but is less certain and more toxic. Aponal, a compound of amylene hydrate and urea (dose 10 to 20 grains), is said to be a safe hypnotic and less unpleasant to take than amylene hydrate; it is rarely used. Hedonal is isomeric with aponal (dose 10 to 20 grains); it is an uncertain hypnotic. Neuronal, diethyl bromide acetamide (dose 5 to 20 grains), is a powerful hypnotic, but has toxic effects on the heart and alimentary system, and causes skin rashes; it has fallen into disuse.

Avertin is tribromethyl alcohol. It has been used extensively as a basal anaesthetic and is administered rectally. The dose recommended by the introducers is 1 1/4 to 1 1/2 grains (0.1 gram) per kilogram body weight of the patient, but there are many conditions which would demand a considerably smaller dose than this. Care and experience are required to decide on the suitable dosage for basal anaesthesia. It may cause prolonged coma, or toxic liver effects such as jaundice in susceptible patients.

THE URÆA GROUP

Urethane (ethyl carbamate—dose 15 to 30 grains) is a mild and safe hypnotic, suitable for children. Alendrin (dichlor-isopropyl carbamate—dose 10 to 30 grains) is little used. Uradal, or adalin, is brom-diethyl-acetyl urea (dose 5 to 15 grains), a sedative as well as a hypnotic; it is a useful and safe hypnotic; I have met with no cases of addiction or toxic effects from its use. Uvaleral or bromural or dormigene is a monobrom-isovaleryl urea (dose 5 to 10 grains); it is a useful and safe hypnotic. Somnosal is a proprietary preparation composed of a mixture of bromural and dimethyl-amido-phenyl-methyl-iso-pyrazolon (dose 5 to 10 grains); it is a mild and safe hypnotic.

* Opening paper in a discussion at the Royal Society of Medicine in the Sections of Therapeutics and Pharmacology and Psychiatry, December 12th, 1933. Published by permission of the Society.

SULPHONE GROUP

Sulphonal is dimethyl-methane-diethyl-sulphone (dose 10 to 30 grains). Trional is methyl-sulphonal (dose 10 to 20 grains). Tetronal is ethyl-sulphonal (dose 10 to 20 grains). These three hypnotics are only slightly soluble in water. They are very slowly absorbed, and their action thereby may be much delayed. They are powerful hypnotics, but owing to their delayed and uncertain action are less used than formerly. They have been much used in asylum practice.

Dangers from this group are a cumulative effect, owing to delayed absorption if the drug has been taken in repeated daily dose, when coma may develop unexpectedly. There are many recorded cases of drug addiction. Repeated use of the drugs may lead to troublesome skin rashes of urticarial or erythematous type, often associated with marked prurigo. Vesicular and bullous eruptions and purpura have been observed. Haemato-porphyrinuria is a common but not constant symptom. Mental depression leading to suicidal tendency and the taking of an overdose may occur. Subjective and objective toxic effects on the nervous system have been observed, such as hallucinations, slurred and thick speech, diplopia, squint, ataxia, drowsiness, and stupor. Overdosage may be followed by deep coma lasting over a prolonged period (several days), and during this period there is danger of the development of basal bronchopneumonia, which is usually fatal. In these cases the drug has been found in the cerebro-spinal fluid. An extensive plantar reflex is common during the stage of coma.

Death has occurred after one dose of 30 grains in a neurasthenic woman. Probably an average minimum fatal dose for an adult is about 75 grains, but recovery has occurred after very much larger doses. Several deaths have followed the daily use of from 10 to 20 grains over periods of from two to twelve months.

THE BARBITURIC ACID GROUP

Barbitone or veronal is diethyl barbituric acid. Sodium barbitone or medinal is the sodium salt of barbitone. Propionyl is dipropyl barbituric acid, and neonal or soneryl is *n*-butyl-ethyl barbituric acid. Dial is diallyl barbituric acid. Phenobarbitone, or luminal, is diphenyl barbituric acid, and sodium luminal is its sodium salt. Phandorm is cyclo-hexenyl-ethyl barbituric acid, evipan is *n*-methyl-C-cyclo-hexenyl-methyl barbituric acid, and sodium evipan is its sodium salt. Pentobarbitone is ethyl-methyl-butyl barbituric acid, and its sodium salt is nembutal. Ipral is calcium ethyl-isopropyl barbituric acid.

Allonal is a combination of allyl-isopropyl barbituric acid with amidopyrine (it gives a reddish-brown colour to the urine from the amidopyrine present). Veramon is a combination of veronal with amidopyrine (it gives a reddish-brown colour to urine). Gardenal is phenyl-ethyl barbituric acid. Cibalgin is a combination of dial and amidopyrine (it gives a reddish-brown colour to urine). Somnifaine is a combination of allyl-isopropyl barbituric acid and veronal. *Beatol* is a proprietary preparation, said to be a mixture of veronal with extracts of valerian and jusquiman. Quadronox is a proprietary preparation said to contain 80 per cent. veronal, with phenacetin, phenazone, etc. (urine may be coloured reddish brown from the phenazone present).

Sandoptal is isobutyl-allyl barbituric acid. Amytal is isoamyl-ethyl barbituric acid; the sodium salt is used for intravenous purposes. Pernocton is 2-butyl-bromethyl barbituric acid; the sodium salt is used intravenously.

Hebaral sodium is the sodium salt of hexyl-ethyl barbituric acid, and is given by the mouth for insomnia. A considerable number of other preparations containing barbituric acid derivatives are on the market. The addition of

alkyl or aryl radicals of higher molecular weight than ethyl adds to the toxicity of the substance; thus luminal dial, propional, gardenal, soneryl, and nembutal are all more toxic than veronal. Launoy and Contière, taking veronal as unity, have found that the relative toxicity for dial is 3.1, for soneryl 4.7, for amyral 10.1, and for nembutal 10.1.

The combination of a barbituric acid compound with an analgesic drug (such as amidopyrine, phenacetin, etc., in veramon, allonal, cibalgin, and quadronox) appears to me to be dangerous, since the barbituric acid compound is much more toxic than the analgesic drug, and this may lead to an overdosage of the barbiturate when the preparation is taken in large doses to relieve pain.

The barbituric acid derivatives are perhaps the most commonly used hypnotics at the present day. When taken by the mouth they are quickly absorbed, and within an hour or so of taking a clinical dose sleep usually ensues. After a single therapeutic dose, a period of sleep, lasting from six to twelve hours, usually occurs without unpleasant after-effects. There is more certainty of action than with most of the other hypnotics. These are the reasons for the popularity of this group of hypnotics.

All of the above group of drugs have been used for hypnotic purposes. When one remembers that the toxicity of the derivative increases with the substitution of larger radicals than ethyl, it is probably safer to use, for hypnotic purposes, barbitone or its sodium salt than the more complex derivatives.

Many of the group mentioned have been used for basal anaesthesia. Those which are most commonly used at the present time for this purpose are nembutal, pernocton, amyral, and evipan.

DANGERS FROM THE BARBITONE GROUP

Like other poisons, if taken on an empty stomach and in solution, the effect is more rapid and intense. The taking of alcohol with the drug seems to increase the toxic effect.

Some persons have a natural increased susceptibility to all drugs; often there is present a highly strung nervous temperament, and there is a history of abnormally excessive reaction to medicinal preparations.

Allergic patients are often abnormally susceptible—for example, a history of asthma, urticarial attacks, angioneurotic oedema, etc., are an indication of this state. With defective renal function the usual symptoms of acute or chronic nephritis may be present, but a chronic cystitis, accompanied by a latent pyelitis, will greatly increase the susceptibility to barbiturates, even if the blood urea is little above the normal. With defective liver function a history of cirrhosis or tendency to jaundice or to attacks of acidosis may be present as an indication. Hyperthyroidism greatly increases the susceptibility to these drugs; for example, nembutal is dangerous as a basal anaesthetic. Myocardial disease also may heighten susceptibility. Glycosuria is evidence of defective pancreatic or hepatic function, and is an indication of likely idiosyncrasy. The prolonged toxic effects of some existing disease greatly enhance the susceptibility of the patient to this group of drugs, especially the basal anaesthetics.

TOXIC EFFECTS ON CENTRAL NERVOUS SYSTEM

Idiosyncrasy may lead to symptoms of acute or sub-acute poisoning from a normal full dose—for example, I have seen prolonged coma, suppression of urine, and bronchopneumonia follow a normal dose by mouth of 2 capsules (3 grains) of nembutal. The repeated use of therapeutic doses not uncommonly causes some symptoms,

such as mental depression, drowsiness, visual hallucinations, vertigo, ataxic gait, thick and indistinct speech (anarthric), diplopia, squint, nystagmus, difficulty in protruding the tongue, paralysis of a limb, facial paralysis, tremors of the hands, etc. Albuminuria sometimes occurs, and rarely haematoporphyria. A reddish-brown-coloured urine is present where a phenazone derivative is combined with the barbituric acid compound. Skin rashes of an urticarial, erythematous, or bullous type may occur.

The symptoms from chronic or subacute poisoning very closely resemble those of organic nervous diseases such as encephalitis lethargica, bulbar paralysis, cerebellar disease, general paralysis of the insane, alcoholism, peripheral neuritis, etc. In 1927 a paper was read before this Section by Dr. F. A. Pickworth, in which it was shown by animal experiments that actual degenerative changes occurred in the nerve cells after the prolonged administration of barbituric acid compounds. This work had been carried out by the late Sir Frederick Mott in conjunction with Dr. Pickworth, and I have no doubt as to its accuracy. There is therefore a pathological basis for the toxic nervous symptoms which are observed clinically.

In healthy persons barbituric acid compounds are fairly rapidly excreted, and accumulation does not readily occur. Where repeated doses are taken, there is an accumulation of the toxic effects as shown by the objective nervous symptoms mentioned. In these cases discontinuance of the drug for a few days leads to disappearance of the symptoms. I have seen toxic jaundice follow the daily taking of 1 grain of luminal for over a year.

Only a slight degree of tolerance to this group of drugs is established even after long use. It is for this reason that a moderate overdose is usually followed by severe symptoms.

I have seen a large number of cases where a definite craving for the drug has arisen after repeated daily administration, and the daily use of the drug has been continued in spite of strong medical advice to the contrary. Addiction to the barbituric acid group of drugs differs from morphine and heroin addiction in that sudden discontinuance is not followed by severe withdrawal symptoms.

I have been very greatly impressed by the risk of fatality from suicide. Persons who have been taking the barbituric acid derivatives daily for a long period very commonly take a large overdose when they are faced with mental stress and worry, and often death results thereby. I have met with such cases where suicide has been effected by taking an overdose of lysol or other poison. The danger of overdosage must always be borne in mind with persons taking barbituric acid drugs in repeated daily doses; it is a very real danger. A recent example of this occurred in the case of a physician whom I saw when a large overdose of veramon was taken with fatal result.

ILLUSTRATIVE CASES

1. F., aged 35, suffering from effects of domestic worry. Had been taking two tablets of veronal nightly for several weeks. Very depressed, tremors of facial muscles, very ataxic gait, visual hallucinations. Symptoms completely cleared up after five weeks.

2. M., aged 34, in an institution for treatment for chronic alcoholism. Had been given alional, four tablets nightly for several weeks. No alcohol taken while in institution. He developed thick and indistinct speech, diplopia, and ataxic gait. Wassermann reaction negative. Symptoms cleared up on discontinuance of alional.

3. M., aged 45, suffering from acute rheumatic fibrositis. Had been given 10 grains of medinal for six nights. On examination drowsy, with bilateral ptosis, speech indistinct and thick, diplopia on looking to left. Mental condition somewhat confused. Had been seeing objects which were

non-existent (visual hallucinations). No history of alcoholism or evidence of syphilis. The symptoms completely cleared up in a week after discontinuance of the medinal.

4. M., aged 60, with history of epilepsy. Had taken 14 grains luminal daily for eighteen months. On examination jaundice present for fourteen days, some abdominal pain in hepatic region. Drowsy for three days. Sick several times daily the last three days. Liver slightly enlarged. This patient was obviously in a condition of commencing acute yellow atrophy. On discontinuance of the luminal, and with intensive treatment with alkalis and glucose, the symptoms cleared up after a few days.

5. F., aged 60, doctor's wife, said to have taken a few (2 six) tablets of dial. On examination four hours afterwards deep coma, loss of conjunctival reflexes. Stomach washed out, strong coffee given, and colon washed out. Consciousness recovered in fourteen hours, when delirium and restlessness occurred. Good recovery.

6. F., aged 65. Operation for gall-stones and intestinal obstruction. Nembutal given intravenously for anaesthesia. On the day after operation, defective articulation; two days after operation, confused defective articulation. Suppression of urine after operation. Death occurred four days after operation.

7. M., aged 55, suffering from chronic streptococcal toxæmia. On December 23rd, 1932, two capsules of nembutal were given. A deep sleep lasting twenty-eight hours occurred. On December 26th one capsule of nembutal was given at noon. On December 27th, at 4.30 a.m., one capsule of nembutal was given, and at 1 p.m. another capsule by mouth. Coma followed in two hours. At 6 p.m.: temperature, 101° F.; respirations, 40. 8 p.m.: temperature, 103°. 9.45 p.m.: temperature, 102°; respirations, 60. Dullness over right lower lobe, deficient air entry, and crepitation. 11.30 p.m.: lumbar puncture, 30 c.cm. of fluid drawn off. December 28th: 6 p.m., recovery of consciousness. Temperature normal. Lung signs beginning to clear up. Retention of urine occurred for four days and some suppression (58 oz. of urine passed in four days by catheter). Good recovery occurred.

8. F., aged 39. Operation for vesico-vaginal fistula, which had been present for nine months. One capsule of nembutal given the night before operation. Two capsules of nembutal given an hour before operation the following morning. Gas and oxygen given also for anaesthesia. After operation deep coma supervened, with all the signs of acute barbituric acid poisoning. Typical pneumonia occurred. Death resulted fifty-one hours after the operation. Blood urea, 57 mg. per 100 c.cm. eighteen hours before death. This was clearly a case of nembutal poisoning, the idiosyncrasy being due to the toxic effects of the genito-urinary infection on the heart and kidneys.

NEED FOR CARE IN USE OF HYPNOTICS

The need for exercising care in the use of hypnotics is obvious, particularly when there are any of the danger signs above mentioned. In psychical cases an obsession of insomnia sometimes occurs, and in such cases ordinary therapeutic doses seem to have little or no effect. It is probable that such cases would be better treated by psychotherapeutic measures than by drugs.

With the drugs used for basal anaesthesia the need for care in dosage cannot be too strongly emphasized. If a therapeutic dose (which in a susceptible person may be an overdose) be given, either intravenously or by mouth, it cannot be withdrawn, since absorption is rapid and one has to combat the full effect of the toxic symptoms. Where any of the dangers mentioned are present, if a basal anaesthetic is used at all, a minimum dose should be given and full anaesthesia obtained by a general anaesthetic such as gas and oxygen or ether.

In a recent case where avertin was desired by the patient, after consultation it was decided to give a half-dose since glycosuria and myocardial weakness were present. Some of the solution was returned after rectal administration, and probably only about one-third of the normal dose was absorbed. This patient was able to talk up to the time of the abdominal operation, which was performed under gas and

oxygen and ether. After recovery from the operation the patient stated that he had no recollection of the events preceding the operation, and a full amnesia was attained with the small dose.

In cases where there is a possibility of danger it appears to me that if a basal anaesthesia is used a reduced dose should be given which would effect amnesia without causing complete loss of consciousness.

CONCLUSIONS

In prescribing hypnotics it is wise to select one or a combination of the less toxic type of drugs whose action is well known. I have been so impressed by their toxic effects that I never prescribe any of the barbituric acid group of drugs or of the sulphonal group.

These drugs should only be obtained on the prescription from the medical adviser, and the prescription should be retained by the pharmacist and not repeated, except on medical authority and signature. The total quantity ordered on a prescription should be well under a possible fatal dose.

Legislation regarding the sale of poisons is under consideration as a result of the recent Pharmacy and Poisons Act, which was passed this year (1933).

A close co-operation between the medical profession and those practising pharmacy is essential if dangers from hypnotic drugs are to be avoided.

CARBON DIOXIDE THERAPY IN LOBAR PNEUMONIA

BY

REGINALD HILTON, M.D., F.R.C.P.

ASSISTANT PHYSICIAN AND ASSISTANT DIRECTOR OF THE MEDICAL UNIT, ST. BARTHOLOMEW'S HOSPITAL.

Of recent years increasing attention has been given to the use of carbon dioxide in respiratory conditions. In some ways it is the ideal respiratory stimulant; its chief action is to increase the depth of breathing without accelerating its rate excessively. This result is apparently achieved in two ways: first, by the changes it produces in the pH of the blood, secondly, by the specific effect of the HCO_3 ion itself. It is therefore to be expected that its value would be tested in many respiratory conditions, in some of which, indeed, its utility has already been fully demonstrated. These include atelectasis, certain forms of asphyxia, and post-operative bronchopneumonia. Its value, however, is still under dispute in lobar pneumonia. This paper is concerned with the latter condition.

Hanson and Calhoun,¹ in a series of early cases treated for short periods by 5 per cent. CO_2 and 95 per cent. O_2 , carefully controlled by repeated x-ray examinations, failed to abort the spread of consolidation. Alison² claimed that the disease could be arrested if treatment were begun in the first thirty-six hours. In his opinion the patients "were more comfortable and appeared to progress better" with CO_2 added than with oxygen only. On the experimental side Henderson³ and others assert that in pneumococcal pneumonia with bronchial obstruction CO_2 prevents the development of the disease. He considers that atelectasis plays an important part in lobar pneumonia. Since hitherto there has been a lack of blood-gas studies in man after CO_2 administration, the following observations attempt to supply some of the missing evidence.

As there is a considerable amount of information about the benefit of O_2 alone, it was considered advisable to study the effects of CO_2 unaided by oxygen. The procedure adopted has been to measure first the rate and depth of respiration. A sample of arterial blood was

then taken from the femoral artery. Approximately 3 per cent. carbon dioxide was administered with a loose face mask, and the examinations of the breathing and the blood were repeated fifteen minutes later. The blood gases were determined by the van Slyke method. There are obvious difficulties in the way of investigations of this sort; for instance, the accuracy of measurements of the tidal air cannot be strict. Any apparatus is apt to disturb a patient with pneumonia, and in particular any resistance to expiration is quickly resented. To obtain the measurements mentioned here a specially devised low resistance mask was employed, which has proved its value in collection of air in dyspnoea.⁴ Some results are shown in the accompanying table.

	Arterial Saturation (Vol. per cent.)		Respiratory Rate per Minute	Litres per Minute Ventilation	Tidal Air in c.cm.
	O_2	CO_2			
1. (a) before CO_2	87	35	41	11.47	280
(b) after (15 minutes later)	88	46	42	15.1	360
2. (a)	91	37.4	21	12.1	390
(b)	82.5	48.2	29	13.75	475
3. (a)	85	32	33	12	365
(b)	85.6	41.5	31	13	420
4. (a)	84	31.4	35	10.4	290
(b)	85.2	43	33	12.05	365

These observations were made during the first five days of lobar pneumonia.

The first point to be noted in the table is that arterial anoxaemia is unrelieved after CO_2 administration in these quantities, in spite of the fact that the depth of the tidal air is considerably increased. This raises the question as to what part shallow breathing plays in the production of anoxaemia.

SHALLOW BREATHING

Haldane, Meakins, and Priestley⁵ have shown that the artificial limitation of the tidal air in normal subjects to about 200 c.cm. resulted in periodic breathing, which was removed by adding oxygen. They also demonstrated that the mixed alveolar air under such conditions may contain a higher pressure of O_2 than would be expected to cause anoxaemia. This they explained by uneven ventilation.

Meakins⁶ investigated the question further in pneumonia by correlating the ventilation with the cyanosis. He considered that the shallow restricted breathing in pneumonia was an important factor in causing the anoxaemia. Since anoxaemia in its turn gradually leads to failure of the respiratory centre and rapid shallow breathing, there is a vicious circle which has to be broken if recovery is to follow. The same observer and Davies⁷ published valuable studies of the tidal air and arterial oxygen in pneumonia. Consecutive examinations of the same patient revealed that, as the cyanosis deepened, the arterial oxygen fell and the breathing became more shallow. In that series of observations there were only two measurements of a tidal air below 200 c.cm.: they occurred on the ninth day, when the patient died. These measurements were associated with respiratory rates of over sixty per minute, which is rare in adults who recover. The lowest tidal air during the first five days in four patients was 220 c.cm. In my experience the breathing of patients with pneumonia during the first few days is often of normal depth or even greater, as the table shows. It must be remembered, also, that when a large part of a lung is solid a given tidal air represents a better ventilation for the remaining lung.

When air ventilation is adequate, CO_2 in the quantities here given evidently cannot raise the alveolar O_2 enough to be reflected in the arterial blood. Even with maximum ventilation with air in the normal subject (breathing 60 litres per minute and 1 litre per breath), it has not been found possible to raise the alveolar O_2 from its normal 100 mm. to above 120 mm. Even this rise would be quite inadequate in treating the anoxaemia of pneumonia. The actual increase of ventilation brought about by the use of CO_2 in pneumonia is far inferior to this. In severe cases of pneumonia with much anoxaemia, as the disease progresses the breathing becomes more shallow. It is not possible to measure the effect of this on the alveolar O_2 of a patient with pneumonia, but the effect of gradual

diminution of the tidal air on the normal alveolar oxygen pressure is shown in the figure. The subject was given an oxygen-rich mixture to breathe in order to avoid any oxygen lack. The breathing was timed at a given rate and the depth was left to regulate itself automatically.

It will be noted that the alveolar O_2 actually rises as the tidal air falls. When the tidal air is at about 230 c.c.m., the alveolar O_2 begins to return towards its original level. Even when the tidal air is 200 c.c.m. and the rate sixty per minute (which may well be termed rapid shallow breathing) the mixed alveolar O_2 is not below the figure at which it began during quiet breathing. On breathing air at the rate of seventy-two respirations per minute and at a depth of only 128 c.c.m. the average alveolar O_2 was 91 mm. Such breathing is far more rapid and shallow than ever occurs in lobar pneumonia in the adult, and yet the mixed alveolar O_2 is but little below the average normal 100 mm.

It is possible that uneven ventilation of alveoli may explain such high O_2 figures, in spite of such a low tidal air, as was shown in the experiments of Haldane on normal subjects; but in the anoxaemia of pneumonia, when there is some alveolar obstruction to the passage of O_2 , there is more chance of compensatory oxygenation in some of the overventilated areas than there is in the anoxaemia of artificially limited breathing. Uneven ventilation is quite inadequate to explain the experiments of Uyeno. This observer, by heating from 35° to 39° , increased a cat's respiration from sixteen per minute to 240: the depth was reduced from 16.7 c.c.m. to 2.7 c.c.m. The minute-volume of the heart stayed at the same level, and the arterial O_2 saturation changed only from 99 per cent. saturation to 92 per cent. These observations tend to minimize the importance usually attributed to shallow breathing in the causation of anoxaemia, and help to explain why CO_2 as given here fails to relieve the condition.

Before leaving the question of the effect of CO_2 on arterial O_2 saturation, there is one more point to be made. If areas of lung collapse played an important part in the causation of anoxaemia in lobar pneumonia, it would be expected that an increase in the tidal air would improve

the oxygenation of the blood by preventing venous short circuits. These observations appear to show that this is not the case.

ACTION OF CO_2 ON THE O_2 DISSOCIATION CURVE

It is well known that CO_2 alters the shape of the O_2 dissociation curve of haemoglobin, but it is difficult to assess the practical importance of this shift to the right. Theoretically it means that the tissues obtain their O_2 more readily. It also means that O_2 is picked up less readily in the lungs. This latter factor would tend to prevent a rise in alveolar O_2 pressure from having the expected result on the arterial O_2 saturation. But on the whole it is probable that changes in CO_2 tension of the order here considered play a part of minor importance in pneumonia with regard to the carriage of O_2 by haemoglobin.

ARTERIAL CO_2

It will have been noted from the table that the arterial CO_2 is low in pneumonia. This provides confirmation of Meakins's original observations. The explanation would seem to be that the increased ventilation has "washed out" the gas, as is well known to occur with overbreathing. This might be due to central or peripheral causes, but we have still much to learn in this connexion about lung reflexes, such as the Hering-Breuer reflex, in pathological states.

Whatever the mode of production there is some evidence that a reduction of arterial CO_2 may have in itself serious effects and its removal therefore bring benefit. Thus Yandell Henderson¹⁰ has dealt in a series of papers with the circulatory failure which results from acapnia or acardia, as he now terms it. Dale and Evans¹¹ have shown that the fall of arterial pressure after severe overventilation is due to depression of the vasomotor centres of the bulb and the spinal cord brought about by removal of free CO_2 , and not to changes in the hydrogen-ion concentration in the blood ("alkalosis"). On the other hand, CO_2 has a direct vaso-dilator action on capillaries. In lobar pneumonia, however, there are other factors influencing the blood pressure, so that the part played by CO_2 lack of itself cannot be analysed at present except by measuring the effect of its administration. One thing is clear: whatever ill effects may be demonstrated as due to acapnia, this state can be removed very rapidly by the addition of small quantities of CO_2 .

CLINICAL EFFECTS

Pain

The increased respiratory effort brought about by CO_2 is apt to distress a patient unless it is kept within narrow limits. Reference to the table shows that CO_2 in sufficient quantity to augment the tidal air by 100 c.c.m. or less will raise the arterial CO_2 by 10 volumes per cent. in a few minutes. Such an increase in depth does not apparently cause much discomfort. In cases of thoracic pain the use of CO_2 would, of course, be contraindicated unless opiates were given at the same time. The use of CO_2 after morphine is helpful in avoiding excessive depression of the respiratory centre.

Blood Pressure

Clinically, the effect of CO_2 on the blood pressure in some cases is very noticeable. A rise of about 20 mm. Hg in systolic pressure was observed. The pulse became fuller. The explanation of this is probably a mechanical one from an increased venous return rather than from any action on the vasomotor centre, for the following reasons: signs of vasomotor failure as shown in experimental acapnia are uncommon in lobar

pneumonia at this stage. Also, a similar rise may be demonstrated in a normal person whose arterial CO_2 is not diminished.

Cyanosis

There is usually little or no change in the cyanosis. What there is cannot be due to increased arterial oxygenation (see table), but might be explained by an increase in the minute-volume of the heart or by a local vasomotor change. Otherwise it is difficult by the bedside to point to any immediate change in a patient as a result of small quantities of CO_2 at all comparable to the effect of O_2 in lobar pneumonia.

CONCLUSION

The practical conclusion of this paper is that in the absence of respiratory failure, as evinced by shallow

breathing, the clinical benefits of CO_2 administration in air are not sufficiently demonstrated by these observations to warrant its routine use in lobar pneumonia.

RENAL TUBERCULOSIS WITH A SURVEY OF SEVENTY CASES

BY

ARTHUR JACOBS, F.R.F.P.S.

UROLOGIST, GLASGOW ROYAL INFIRMARY; UROLOGICAL SURGEON,
GLASGOW ROYAL CANCER HOSPITAL

Renal tuberculosis is an insidious disease, for the focus in the kidney is usually well established before its presence gives rise to symptoms. In the majority of cases the outstanding symptoms are referred to the bladder, and consist of increased frequency in urination, with pain before and after the act. The frequency may be variable, but tends to increase, and, as the disease progresses, the patient may require to urinate as often as every twenty minutes, night and day. The urine is acid or neutral, contains albumin and pus, and, frequently, blood. Pain in the renal area is often absent altogether, or is insignificant in degree. Usually a diagnosis of "cystitis" is at first made, but the symptoms fail to respond to the medical treatment commonly prescribed for this complaint. All such cases of persistent frequency, particularly when occurring in adults between 20 and 40, should be suspect.

It is the present consensus of opinion that a normal kidney cannot filter tubercle bacilli from the blood stream into the urine. If, therefore, tubercle bacilli are found in the urine, and a genital tuberculosis can be ruled out, a renal focus must be present, because there is no such thing as a primary tuberculosis of the bladder. Recognition of a genital tuberculosis in the male is usually easy, but it should not be forgotten that this condition is frequently accompanied by a coincident renal infection. In the female the diagnosis of a genital tuberculous lesion may not be so obvious. In the following case a tuberculous cystitis was found to be secondary to infection of a Fallopian tube.

A woman, aged 24, a school teacher, was referred for consultation because of a persistent frequency and dysuria of one year's duration; she required to urinate several times in an hour. She had had a period of sanatorium treatment in Switzerland four years previously for pulmonary tuberculosis, but it was considered that this lesion had healed. The urine contained a heavy deposit of pus. Examination of numerous smears failed to reveal the tubercle bacilli, but a guinea-pig inoculation was positive. Cystoscopy showed a generalized cystitis, and, in places, superficial ulceration. There was considerable adherent purulent lymph on the right side. The base of the bladder to the right of the left ureteric orifice was markedly elevated. The ureteral orifices looked normal, and both ureters were catheterized to the renal pelves. An abundant flow of clear urine came from either side, and both specimens were found to be free from pus, and sterile. Bilateral ascending pyelograms were normal. The x-ray films, however, showed a large, rounded, calcareous shadow in the left side of

the pelvis, above the level of the ischial spine. It was obvious that the tuberculous cystitis was not of renal origin. The diagnosis was settled by a vaginal examination, which revealed an extensive pelvic mass, due to a tuberculous pyosalpinx.

The discovery of the tubercle bacillus is not essential in order to establish a diagnosis. The presence of pus in the urine, but no organisms, is strongly suggestive of a tuberculous infection, and a guinea-pig inoculation should be made. I cannot, however, agree with Wade, who states that "if, on examining the cellular deposit, no organisms are found in it, it is safe to assume that the infection is tuberculous and that you have failed to detect the causal virus."¹ This infers that every case of aseptic pyuria is tuberculous; contrary to this, I have had under observation several such cases, in which an investigation of the complete urinary tract, including guinea-pig inoculation, failed to reveal evidence of a tuberculous lesion.

Since January, 1928, I have seen in hospital and private practice seventy cases of tuberculosis of the kidney. Forty of the patients were males and thirty females; forty-eight were between 20 and 40 years of age, ten were under 20 (the youngest being 7), nine were in the fifth decade, and three in the sixth. Renal pain was a symptom in twenty-two, and in four of these bladder symptoms were absent. The tubercle bacillus was found by examination of direct smears of the centrifugized urine in forty-five, and by guinea-pig inoculation in another ten. The only specimen submitted to the bacteriologist in many instances was the urine taken from the bladder at cystoscopy. The proportion of positives would undoubtedly have been higher if further specimens, taken from twenty-four-hour collections of urine, had been examined. Thirteen patients out of forty-six who were subjected to nephrectomy had the operation performed in the absence of positive urine findings. In two of these a pre-operative diagnosis of hydronephrosis had been made, and the tuberculous nature of the lesion recognized only at operation. In the other eleven a correct pre-operative diagnosis was made in the absence of the positive urine smears, and without waiting for confirmation by animal inoculation.

INVESTIGATION OF A CASE OF RENAL TUBERCULOSIS

(A) *Cystoscopy*.—The appearances of the bladder in cases of renal tuberculosis often make a diagnosis possible in the absence of the causal organism. The evidence thus obtained is frequently characteristic and of immediate diagnostic significance. The first point usually noticed is the reduced capacity of the bladder, which normally is eight to twelve ounces. In addition, the viscus is easily irritated, so that, if too quickly filled with the distending lotion, spasm is induced and completion of the cystoscopy may be prevented. Generally speaking, if the capacity is

less than two ounces cystoscopy is impossible. Where renal pain rather than urinary frequency is an outstanding symptom it is common to find little or no impairment in the bladder capacity. This may be due to the bladder having successfully resisted the infection, or to occlusion of the ureteric orifice on the diseased side. There may then be no appreciable bladder manifestations of the condition. The appearance of the ureteral orifice on the involved side is usually altered. At first it is swollen, reddened, and congested. Tubercles may infrequently be observed near or on the margin. As a result of ulceration the latter becomes irregular, and the meatus gapes; the meatus may, however, become almost closed by oedema of the surrounding mucosa. Finally, the orifice becomes dragged upwards as a result of contraction occurring in the affected ureter, and an appearance aptly described as "golf-hole ureter" obtains. The changes in the bladder itself are not usually of a specific nature. Thus it is only occasionally that tubercles are actually observed. Ulceration following rupture of the tubercles is more frequently seen either in the vicinity of the ureteric orifice or on the fundus. The margins of the ulcers are undermined, the edges irregular, and a slough may occupy the base. Bullous oedema is very common, and may cause the ureteric orifice to be entirely hidden from view. Later, if secondary infection occurs, exuberant polypoid excrescences may form, and may render the ureteric orifices unrecognizable. The whole of the vesical mucosa will then become involved in the inflammatory process, and will look reddened, swollen, and lustreless. This is the stage at which a large percentage of the cases are sent for investigation. The impaired capacity and irritability of such bladders present the cystoscopist with one of his most difficult tasks.

(B) *The Indigo-carmin Test.*—This is of little value in making a diagnosis. It may be useful in helping to locate the diseased side, when the data to be had from the appearance of the orifices are not sufficient, or when the inflammation is so generalized that both sides appear to be affected. I do not consider that a normal dye secretion proves that the corresponding kidney is free from infection. Conversely, a delayed and weakened secretion does not necessarily mean that the kidney is infected. The function of the non-tuberculous kidney may, for example, become impaired from a secondary nephritis, or from dilatation due to back pressure resulting from contracture of the inflamed bladder, and these conditions can be responsible for impairment in the elimination of the dye.

(C) *Catheterization of the Ureters.*—This is the most important step in the whole examination. It is done in order to obtain specimens of the secretion from the separate kidneys for bacteriological and cytological examination, as well as for the urea concentration test. The catheters should be passed up the ureters to the renal pelves, and the urines collected in the second hour after a urea meal (15 grams of urea and 100 c.cm. of water). If leucocytes and tubercle bacilli are absent from one side the disease may be regarded as unilateral. Suspicion must be entertained if leucocytes alone are present, and a guinea-pig inoculation should be carried out. When cystoscopy and intravenous pyelography (see below) reveal a definite involvement of one side, I consider that it is only necessary to catheterize and obtain specimens from the supposedly healthy kidney. If 2 per cent. or more of urea is discovered in the urine the function of the kidney may be regarded as satisfactory.

(D) *Pyelography.*—I do not carry out ascending pyelography as a routine in tuberculous cases, because of the supposed possibility of disseminating the causal virus from the diseased kidney into the circulatory system. Moreover, the examination in many instances is superfluous.

I have no hesitation in using it on suspected cases, however, when there is failure to demonstrate the tubercle bacillus, and I am unaware of any harmful sequelae resulting. The pathognomonic pictures usually obtained frequently allow of an immediate and definite diagnosis. Since the advent of intravenous pyelography I have employed this method, either as a first step in the investigation of cases known to be tuberculous or as an additional check-up after cystoscopy and ureteral catheterization. The radioscopic appearances obtained in this way vary greatly with the phase of the disease. Experience teaches one to recognize as characteristic certain features, such as thinning and lack of definition in the calyces, knobbing and woolliness in their terminal ends, irregular dilatation and fuzzy outline in the renal pelvis, and areas of dilatation and constriction in the ureter. Minor defects which would be observed with the ascending method may not, however, be apparent. The indefiniteness of the shadow frequently makes it impossible to form an opinion as to the nature of the lesion without the help of cystoscopic data. In certain unilateral cases the dilatation in the ureter and pelvis that can occur in the other kidney as a result of back pressure from a contracted bladder may, with an intravenous pyelogram, give an erroneous pictorial impression of bilateral disease. If there is very advanced renal destruction, then, of course, no picture at all is obtained by the intravenous method.

Diagnosis.—The object of the urological examination is to confirm the diagnosis of renal tuberculosis, and to ascertain whether the disease is unilateral or bilateral. It is desirable that this information be obtained with the minimum possible instrumentation. In cases in which the tubercle bacillus is known to be present in the urine it may, as I have indicated, be sufficient to make an intravenous pyelographic examination, followed by a cystoscopy and catheterization of the ureter from the apparently healthy kidney. If the secretion from that side be uninfected, a diagnosis of unilateral tuberculosis can be made. In the event of an intravenous pyelogram giving conclusive evidence of a bilateral involvement, instrumental examination may not be required at all.

Illustrative Cases

Case 1.—Female, married, aged 34, was referred from the out-patient department, where she had been sent because of frequency and dysuria of seven months' duration. The nocturnal frequency was five to six times, the diurnal hourly. A bacteriological examination of the urine had already been made and tubercle bacilli found. Intravenous pyelographic studies showed extensive dilatation in all the calyces of the left kidney; the right side looked normal. At cystoscopy, carried out in the second hour after a urea meal, the bladder capacity was found to be reduced to 50 c.cm. There was a generalized inflammation, but both orifices looked normal. A catheter was passed up to the right renal pelvis, and specimens of clear-looking urine collected. Subsequent examination of the specimens was negative for pus cells or for tubercle bacilli, and the urea concentration was 4.3 mg. per cent. The diagnosis was therefore a left renal tuberculosis. The absence of infection in the right kidney was further confirmed by a guinea-pig inoculation with some of the urine taken from that side, which proved negative for tubercle.

Case 2.—Male, labourer aged 34, complained of frequency of micturition and dysuria of twelve months' duration. The nocturnal frequency was two-hourly, the diurnal hourly. He had had excision of tuberculous cervical glands in childhood. The urine contained albumin, pus, and blood. The bladder capacity was 175 c.cm. There was a mild generalized cystitis. A deposit of mucus-pus lay on the base behind the inter-ureteric bar. The left orifice looked dilated, the right normal. A mediumly concentrated secretion appeared at the right ureteric orifice five minutes after an intravenous indigo-carmin injection; no dye appeared from the left orifice after ten minutes' observation. The specimen

of urine collected at the examination was found to contain tubercle bacilli. At a subsequent cystoscopy a specimen was collected from the right kidney. This had a urea concentration of 2.4 mg. per cent., and contained pus cells and tubercle bacilli. A diagnosis of bilateral renal tuberculosis was therefore made.

Case 3.—Male, aged 7, referred from the sanatorium, where he had been under treatment for the previous eight months. He was complaining of generalized abdominal pain, and frequency of two years' duration. He was considerably emaciated. A guinea-pig inoculation had proved positive for tuberculosis. A series of intravenous pyelographic studies was made. Films were exposed after 5, 10, 20, 40, 60, 90, and 105 minute intervals. The left kidney pelvis and ureter were visible onwards from the first film. The pelvis and calyces were grossly dilated, and the ureter was about the calibre of the small intestine. The right shadow was not apparent until the forty-minute film was taken. The dilatation on that side proved to be even greater than on the left. This was deemed to be sufficient evidence of extensive bilateral involvement, and further investigation considered unnecessary.

Case 4.—Female, aged 28, complained of attacks of right renal pain of five weeks' duration. For the previous nine months she had been suffering from intermittent bouts of frequency, which would clear up spontaneously. The urine contained albumin and pus, but was sterile. The bladder capacity was 250 c.cm. The right ureteric orifice was dilated and its margin injected, otherwise the bladder appearances were normal. Catheters were passed up both ureters, and specimens collected from each kidney. The secretion from the right kidney was definitely cloudy, that from the left clear. A bilateral ascending pyelographic examination was made. On the right side the pelvis was slightly dilated, the calyces were all clubbed, and the upper group had a "moth-eaten" appearance. The appearances on the left side were normal. The urine from the right kidney was found to contain a considerable amount of pus, but no tubercle bacilli. Some diphtheroids grew on culture. The left kidney urine contained no cells or organisms, and no growth on culture. A diagnosis of right renal tuberculosis was made because of the pathognomonic appearances of the pyelogram.

TREATMENT

The important clinical fact in the treatment of renal tuberculosis is that, with the exception of cases of the miliary type, only one kidney is involved in an appreciable percentage of sufferers. In making this statement I am not unmindful of the evidence which has been brought forward in recent years to show that, pathologically speaking, the disease is frequently, if not always, bilateral, and that small lesions in the apparently normal kidney can often be found when the opportunity arises to examine it.² But a caseo-cavernous renal tuberculosis is usually unilateral in its early stages, and although it may be possible for a small incipient tuberculous lesion in a kidney to heal, it has never been shown that this can occur with a clinical demonstrable caseous focus. In the majority of cases, if the condition is not successfully combated, there is a progressive spread of the disease throughout the genito-urinary tract. When the bladder becomes seriously involved the patient may be reduced to a state of misery and discomfort seen in few other conditions. If, however, nephrectomy is carried out, a cure can be obtained, and the secondary bladder lesions, if not too far advanced, often heal spontaneously.

As it is considered that renal tuberculosis is always part of a general tuberculous infection,* and that the disease is at least latent in other organs, such as the lungs or mediastinal glands, every patient after operation should have a prolonged period of treatment by means of rest, open air, and nutritious diet. Confinement to bed for

from one to six months is advisable, the period varying with the response of a patient to the operation. A course of tuberculin treatment, given over a period of from eighteen months to two years, may have a beneficial effect on the bladder.

Advanced bilateral renal tuberculosis is not usually a surgical condition, though occasionally a nephrectomy may be justified when there is severe pain, haemorrhage, or obstruction on one side. Such a patient should have sanatorium treatment in the hope that, by building up the defence mechanism, the lesions may be controlled. If this is successful, bilateral disease may be compatible with life, and even with useful work, for a number of years.

Of the seventy cases that I have investigated forty-seven were found to have a unilateral infection and twenty-one were bilateral. The data in the other two cases were incomplete, as the patients refused the necessary examination. Thus the percentage of unilateral infections (69 per cent.) was considerably lower than the figure commonly quoted, which is 80 to 90 per cent.³ This question of the relative frequency of bilateral involvement is of the utmost importance, and will be referred to again under prognosis.

RESULTS AND SEQUELAE OF NEPHRECTOMY

Of the forty-seven patients suffering from a unilateral infection, I operated on forty-five and removed the affected kidney. Surgical intervention was not advised in one case because of multiple calculi in the other kidney, and in the other it was refused by the patient. There was one death after operation, and this occurred on the fourth day from duodenal ileus (necropsy). Only one case of advanced bilateral disease was subjected to operation. This was in a woman of 41, who suffered from constant severe left renal pain and begged for relief. It was thought that the right kidney was capable of carrying on the total renal function, as it concentrated a medium-blue dye within ten minutes of an intravenous indigo-carmin injection. The patient, however, never secreted more than two ounces of urine in twenty-four hours after operation, and, in spite of a nephrostomy on the remaining kidney, died on the tenth day.

Healing of the Lumbar Wound

A frequent cause of disappointment after nephrectomy for renal tuberculosis is the breaking down of the wound and the development of slow-healing sinuses. Even when the wound heals per primam a breaking-down may occur several weeks or even months later. This is a universal experience, though scantily referred to by many authors. The complication has apparently little effect on the end-results, but is serious in that it may cause a very protracted incapacity in a patient who would otherwise be well. Crabtree and Cabot² reported only 25 per cent. out of seventy cases as healing by first intention, and Scholfield⁶ reported 40 per cent. out of fifty-seven cases. Twenty-nine of my cases healed by first intention, but ten of these developed sinuses in periods varying from two weeks to two months after operation. Thus the percentage healing by first intention and remaining healed was 42. Post-operative drainage was carried out in ten cases, and six of these developed sinuses; thirty-five were closed without drainage, and out of that number sinus formation occurred in twenty. Neither the presence nor the absence of drainage would therefore appear to be more favourable to sound healing.

Scholfield considers that persistent sinuses are not due to the continuation of the infection from the ureter or from the perinephritic fat, but rather to the development of a new tuberculous process in the traumatized tissues

* Coexisting tuberculous lesions in other parts were noted as follows: pulmonary, seven cases; testicular, five cases; knee-joint, three cases; hip-joint, two cases; sacro-iliac, one case; cervical glands, one case; tibia, one case; foot, one case; cutaneous, one case.

of a patient with a lowered resistance. Removal of the complete ureter, as sometimes advocated, will certainly not ensure healing. One of my patients still has discharging sinuses four years after ureterectomy performed twelve months after removal of the kidney. In most cases, however, with persistent antiseptic treatment, the wound will heal within the year. This has occurred in all but three of my cases: one of these was the patient referred to above, whose wound has been discharging for four years; one other remained unhealed for two years; and another for twenty months.

Effect on the Bladder

Most patients suffering from renal tuberculosis seek relief because of bladder symptoms, and they naturally expect that, after operation, the frequency and dysuria from which they have suffered will be alleviated. After nephrectomy the secondary bladder lesions often heal spontaneously, and the symptoms for which they have been responsible progressively abate. Sometimes this occurs almost immediately, but usually it is a gradual process. It has been stated by Wildbolz⁷ that the bladder may take two to five years to heal. Cystoscopy may show areas of persistent localized ulceration to be responsible for the continuation of the bladder symptoms, and their healing may be brought about by light fulguration. When no such localized lesion can be found, instillations into the bladder of an antiseptic sedative, such as gomenol oil, may be helpful.

In some cases, because of the diffuse inflammatory involvement of the bladder walls, the viscus becomes so contracted that a normal frequency can never be obtained. The pain on urination usually disappears, however. This state of chronic contraction in the bladder renders the remaining kidney liable to a progressive back-pressure destruction. This sequela is well illustrated in the following case.

A girl of 20, who had had a left kidney removed for tuberculosis four years previously, was referred because of total urinary incontinence. This condition had gradually replaced the frequency which had been present prior to her operation. She never at any time passed a proper stream of urine from the bladder, but was constantly wet from dribbling. There was no pain. The urine contained pus and *B. coli*, but no tubercle bacilli, and a guinea-pig inoculation was negative. A cystoscopy was found to be impossible, as the bladder could not be made to retain a drop of fluid. An intravenous pyelographic examination showed an enormous distension of the right renal pelvis and of the complete ureter.

In one case of this series, where there was no appreciable amelioration in the bladder symptoms after the removal of a kidney which was the seat of an extensive caseous destruction, I carried out the operation of resecting the presacral nerve. The result has been most satisfactory.

The patient, a woman of 42, lived in the country and, after the nephrectomy (which was performed in January, 1932), was treated most assiduously by her doctor with tuberculin and instillations into the bladder. She continued to have an hourly frequency night and day, and suffered from a constant irritable feeling in the urethra and severe pain on urination. Tubercle bacilli were still being secreted in the urine, and there was a generalized hyperaemia of the bladder mucosa, which bled easily. There were two localized ulcerated areas present, and I treated these with diathermy without giving any relief. Two months later I carried out the presacral resection. The dysuria disappeared immediately and the frequency became a three-to-four-hourly one. This complete cessation of symptoms has continued since the operation.

PROGNOSIS

How many patients are permanently cured of their urinary tuberculosis by removal of the diseased kidney? In a paper by Wildbolz⁷ of Bern, in 1929, details were given

of 270 cases, all of which had been operated on at least ten years previously, and many dated back to over twenty years. It was claimed that 59 per cent. of these 270 patients were alive, and, with the exception of three, were free from any evidence of urinary tuberculosis. As against this the mortality of unoperated unilateral cases is, according to Person,⁸ 82.5 per cent. within five years.

None of the cases in my series goes back further than six years, but the follow-up which has been carried out has elicited some interesting data. Out of the forty-five unilateral cases that were nephrectomized four have died. Death occurred in two months, nine months, thirteen months, and two years respectively after operation. By a curious coincidence these four cases all belong to the 1931 group. A necropsy was performed on only one of these—namely, on the patient who succumbed two years after operation. He had continued to have bladder symptoms, and a positive tubercle bacilli urine. He refused to go to a sanatorium, and carried on with his work as a road labourer. Three weeks after last reporting he was admitted to Duke Street Hospital suffering from tuberculous meningitis. The necropsy confirmed this diagnosis. The remaining kidney was reported to be macroscopically studded with tubercles. The patient who died two months after operation had active pulmonary tuberculosis, and had been resident in a sanatorium until immediately before the operation. This was carried out under spinal anaesthesia, and, following a rapid recovery, he was transferred back to the sanatorium on the tenth post-operative day. Death was reported to be due to generalized tuberculosis. Information about the cause of death in the patient who died nine months after operation was not available. The patient who died in the thirteenth post-operative month was a boy of 12, and he also appears to have succumbed to a generalized tuberculous infection, though definite details were not obtained.

Taking into account the one post-operative death, there are left forty survivors out of forty-five cases. All have been traced except a girl of 18, operated on in 1929, and last seen in May, 1931, when she was in excellent health, had a four-hourly frequency, and a tubercle-free urine. One patient, operated on four years ago, has developed a faecal fistula in the lumbar wound, and is considered to be dying; in her case also the urine is tubercle-free. Of the remaining thirty-eight cases, twenty-one were operated on before the end of 1932, and twenty of these have had the urine examined within the past few months. In four the organism was found in examination of direct smears, and in five others by guinea-pig inoculation. Thus nine out of twenty cases which were considered to be unilateral are still secreting tubercle bacilli, although the offending organ has been removed. The general condition of eight of these patients is very good: they have, on an average, a two-hourly frequency, and no dysuria. This group includes the patient upon whom a resection of the presacral nerve was carried out. The ninth case has a frequency which varies intermittently from half- to two-hourly, and he also suffers from dysuria.

If the percentage of cases with post-operative positive urines is added to the percentage seen in the same period which were found to be suffering from a clinically bilateral infection, then the relative frequency of the latter would appear to be in the neighbourhood of 57 per cent. If my interpretation is correct, the conception held, until recently at any rate, by most urologists, that renal tuberculosis is, as a rule, a unilateral disease, is erroneous. This, however, does not, in my opinion, infer that a nephrectomy is indicated in only some 43 per cent. of cases, for I consider that a kidney which is the seat of a well-established destructive lesion should be removed,

even if the other side is secreting an occasional bacillus of tuberculosis. If such a kidney has a normal anatomical outline on pyelography, exhibits a good renal function, and is secreting little or no pus, the case can be regarded, clinically, as a unilateral one, and a nephrectomy should be carried out. The marked improvement in most of the nephrectomized patients, even though they still have the organism present in the urine, supports this contention. Further support is to be had, I think, from a follow-up of unoperated cases, which were considered, clinically, to be bilateral. An endeavour was made to trace fourteen such cases which had been seen in the years 1928 to 1931 inclusive. It is significant that it was possible to ascertain the fate only of eight, and of these five had died. Of the remaining three, one was in poor health and had a discharging lumbar sinus, following on the rupture of a perirenal abscess. The two others, although still in fairly good general condition, had a half-hourly frequency night and day.

CONCLUSIONS

1. Renal tuberculosis is clinically bilateral in at least 30 per cent. of cases.
2. A case should be regarded as unilateral, and be nephrectomized if the kidney secretion from one side does not contain pus or tubercle bacilli, and if the pyelographic appearances of that side are normal.
3. The presence of tubercle bacilli without pus in the urine of a kidney which has a normal pyelographic outline should not negative removal of the other kidney if it is the seat of an established destructive lesion. The kidney which exhibits occasional bacilli of tuberculosis in its secretion as the sole evidence of its involvement has probably only an initial tuberculous lesion, and it has been demonstrated that these frequently heal.
4. All patients after operation should undergo a sanatorium regime. This is particularly necessary if sinus formation occurs in the wound and if bladder symptoms persist.

My thanks are due to Dr. Robert Cruickshank, bacteriologist, Glasgow Royal Infirmary, under whose supervision all the bacteriological work has been done. I also wish to thank Mr. Mack, assistant in the urological department and McCum Research Scholar (in bacteriology). He has, during the past year, undertaken a considerable share in the bacteriological investigations, assisted at the examinations and operations, and enthusiastically helped in the follow-up of cases.

A new edition of the well-known handbook of the American Medical Association of Vienna has been issued to cover the academic year 1934-5. It is based on the June, 1931, edition, revisions, corrections, and additions having been effected to bring it up to date. Written in English, it affords a detailed and comprehensive guide to the medical and cultural opportunities for training in that University, special attention being devoted to courses of instruction given in English. For German-speaking visitors details are given of the university courses which are open to them, as also of the many facilities for private tuition and study. Various items of general information reveal the magnitude of the help rendered by this society, membership of which carries various privileges as regards study in Vienna. Copies of the handbook may be obtained from the headquarters of the American Medical Association of Vienna, Alserstrasse 9, Vienna VIII.

THE EFFECTS OF SUBCUTANEOUS AND INTRAVENOUS INJECTION OF TOXINS COMBINED WITH FINE EMULSIONS OF OILS

BY

V. G. WALSH, M.B., B.Ch., B.Sc.

AND

A. C. FRAZER, M.B., B.S.

(From the Department of Physiology, St. Mary's Hospital Medical School)

Experimental work has been carried out by many investigators on the adsorption of toxic substances by colloidal suspensions, and finely divided charcoal and kaolin have been used with considerable success for the adsorption of toxins in the intestinal tract. Particles of kaolin carry a negative charge, and cholera toxin, acting like a positively charged colloid, is adsorbed by the kaolin, and is consequently not absorbed by the intestinal mucosa. Finely divided charcoal will adsorb both tetanus and diphtheria toxins *in vitro*.

AIM OF INVESTIGATION

In order to investigate the properties of finely divided fat particles with regard to the adsorption of toxins and at the same time to overcome the difficulties attendant on the use of solid particles for injection purposes, experiments were conducted with very finely divided emulsions of cod-liver oil, arachis oil, and olive oil. Toxins, such as diphtheria and tetanus toxins, adsorbed on to these fat particles were found to be non-toxic when injected subcutaneously in large doses. The emulsions used in the following experiments consisted in all cases of 3.5 per cent. oil in water, using sodium carbonate as the emulsifying agent, the finished emulsions being adjusted to pH 8 (using the indicator method). Emulsions were prepared with the apparatus previously described by the authors,¹ the oil being very finely dispersed, the size of the particles averaging $1/2$ to 1μ . These emulsions are extremely stable, and will withstand sterilization by boiling.

First Series

Eight rabbits were selected and divided into two groups, A and B. Group A consisted of two rabbits; Group B of six rabbits. Group A—The animals in this group were given a subcutaneous injection of 5 minimum lethal doses of diphtheria toxin mixed with 0.5 c.cm. normal saline. Group B—The animals in this group were injected subcutaneously with 5 minimum lethal doses of diphtheria toxin mixed with 0.5 c.cm. cod-liver oil emulsion. Results: Group A—Death of both animals within thirty-six hours; Group B—No toxic symptoms shown by any of the animals, and all survived.

Conclusion 1.—The toxin-emulsion mixture was non-toxic when injected subcutaneously.

The experiment was now repeated, the animals being divided into Groups A and B as before, but on this occasion the injections were given intravenously. Group A animals were given 5 minimum lethal doses diphtheria toxin with 0.5 c.cm. normal saline injected into ear vein. Group B animals were given 5 minimum lethal doses diphtheria toxin with 0.5 c.cm. cod-liver oil emulsion injected into ear vein. Results: Group A—Death of both animals within twenty-six hours; Group B—Death of all animals within about the same period.

Conclusion 2.—The addition of emulsion to the toxin afforded no protection when the mixture was given intravenously.

This experiment was again repeated. Group A and Group B received the same dose as before, but on this occasion the injections were given into the peritoneal cavity. Results: Group A—Death of both animals in about thirty hours; Group B—Death of all animals in about the same time.

Conclusion 3.—As in the case of the intravenous injection no protection was afforded by the emulsion when given intraperitoneally.

A series of guinea-pigs was now injected, using olive oil and arachis oil emulsions. The dose of toxin was increased up to 20 minimum lethal doses. The results were similar to those of the previous experiments. When the injection was given subcutaneously the guinea-pigs survived; when given intraperitoneally they died in every case.

Second Series

These experiments were now repeated using tetanus toxin. The animals were divided into Groups A and B as before, Group A being the controls injected with the toxin and saline, and Group B injected with toxin and emulsion. Results when the injections were given subcutaneously: Group A—Both animals died; Group B—No toxic symptoms, and all the animals survived. Results when the injections were given intravenously or intraperitoneally: All the animals in both groups died.

Third Series

Experiments were carried out using the toxins as before, but on this occasion a coarse emulsion, prepared by shaking, was used. The dose of toxin was the same as in the previous experiment. When the toxin and coarse emulsion were injected subcutaneously the animals died after a slightly longer period than the controls.

Conclusion 4.—Emulsions consisting of very large globules of fat do not appear to afford any protection.

Discussion

These experiments show that large doses of toxin, which would normally cause death, can be given subcutaneously in conjunction with finely divided oil in water emulsions without producing any toxic symptoms. This power of emulsions to diminish the toxicity of toxins might be due either to the destruction of the toxin or to the adsorption of the toxin on to the surface of the oil globules, only allowing a gradual liberation of the toxin from the site of inoculation. That the toxin is not destroyed by the emulsion is shown by the fact that if the toxin-emulsion mixture is injected intravenously or intraperitoneally the animals die almost as rapidly as when the toxin alone is given. If the emulsion alone is injected intravenously there are no ill effects. The degree of dispersion of the oil in the emulsion is of importance with regard to the adsorption of the toxin. When emulsions consisting of large globules, such as those prepared by shaking, are used and injected with toxin subcutaneously, adsorption does not occur, and the usual toxic effects are evidenced. Since for these experiments the animals used were mainly rabbits, which are not suitable for the investigation of the formation of anti-toxin, the question of active immunization cannot be discussed at this stage. Experiments are now in progress with suitable animals in order to investigate this point.

This action of emulsions upon toxins suggests their use with vaccines. Experiments were carried out on rabbits, using a typhoid vaccine, consisting of typhoid bacilli brought into solution by the hydrotropic action of sulphonated lauryl alcohol and mixed with 5 per cent. olive oil emulsion. The agglutination antigen was in no case impaired, as evidenced by a positive agglutination

reaction in high titres in all cases. Preliminary injections of tuberculin B.E. with emulsions showed that large doses could be administered without causing a severe reaction. Clinical investigations are now in progress, using tuberculin (bacillary emulsion) and 5 per cent. olive oil in water emulsion. The report of the following case serves to illustrate the effect produced.

CASE REPORT

G. T., aged 37 years, female (Dr. A. B. Porteous's case), was a long-standing case of pulmonary tuberculosis. She was first treated in 1928 and sent to a sanatorium for nine months. The patient discharged herself and returned to work for one year. There was haemoptysis in May, 1930, and she was admitted to hospital, where she has been ever since with pyrexia for over three years. Tubercle bacilli were found in sputum. There is evidence of other tuberculous lesions in the kidneys and elsewhere. She has been treated with: (1) emulsion injected intravenously; (2) tuberculin; (3) large doses of tuberculin with olive oil emulsion.

1. *Intravenous Emulsion.*—On several occasions 5 per cent. cod-liver oil and olive oil emulsions were injected intravenously. The temperature fell after the injection, but the effect was not prolonged.

2. *Tuberculin Injections.*—Prolonged treatment with tuberculin B.E. gave no beneficial result. The dose was brought up to 1/750 mg. B.E., when a reaction occurred. The dose was reduced and treatment carried on intensively for five months, injections being given every other day. The patient showed very little improvement. A further series of small doses of tuberculin were given at weekly intervals, but without any apparent benefit. At this stage it was decided to increase the dose of tuberculin mixed with emulsion, assuming, on the evidence quoted earlier in this paper, that the toxic effects might thus be eliminated.

3. *Large Doses of Bacillary Emulsion with Olive Oil Emulsion.*—The first injection of 1/50 mg. B.E. mixed with 2 c.cm. olive oil in water emulsion was increased in subsequent injections to 1/13 mg. B.E. In no instance did a reaction occur, but, on the other hand, the temperature invariably fell 2° to 3° F. within a few hours of injection and remained at a lower level for a period of about four days, when pyrexia gradually increased.

We cannot too strongly emphasize that this case is reported merely to point out that large doses of tuberculin B.E. can be administered with emulsion without causing the general reaction which would occur even with smaller doses of tuberculin injected without emulsion. The use of emulsions for intravenous injection in toxæmia is mentioned in the case reported. The toxin would appear to be adsorbed on to the fine oil particles, but the effect is of a temporary nature. The use of emulsions in certain toxic conditions is under investigation.

SUMMARY

1. Upon subcutaneous injection of large doses of toxin with emulsion no toxic symptoms developed; when given intravenously or intraperitoneally the usual toxic symptoms were evident.

2. In order to afford protection on subcutaneous injection the oil used must be highly dispersed in the emulsion.

3. Large doses of tuberculin B.E., when administered mixed with olive oil emulsion, do not give the general reaction which much smaller doses of B.E. cause when the tuberculin is given alone.

We wish to express our thanks to the Glaxo Research Laboratory for its helpful assistance in providing the emulsifying apparatus and to Professor Collingwood for the facilities provided in his department.

TEN YEARS OF MALARIAL THERAPY

BY

J. ERNEST NICOLE, L.M.S.S.A., D.P.M.

AND

E. J. FITZGERALD, M.D., B.Ch., B.A.O. N.U.I.

ASSISTANT MEDICAL OFFICERS, WINNICK MENTAL HOSPITAL

The malarial treatment of male neurosyphilitics was begun here in 1923. The first year's results were recorded by Dr. T. W. Davidson, and a review of the first three years was published by Dr. J. P. Steel and one of us (J. E. N.). A summary of the whole ten years is given below, the findings as far as convenient being expressed in tabular form, so that only a few remarks are necessary.

The cases under care numbered 368, of which 330 were general paretics and tabo-paretics, the remainder being tabetics and meningo-vascular syphilitics. Except in Table I, no distinction has been made between these two classes, for not only did general paralysis account for the vast majority of the cases, but to distinguish between certain atypical forms of general paralysis and other kinds of neurosyphilis is often very difficult. Many of the cases were admitted in a late stage of the disease; a third were bed-ridden on admission, and nearly two-

thirds were wet and dirty in their habits. A third of the patients were over 50 years of age, twelve being over 60.

TREATMENT

Nearly all the patients were given courses of mercury, iodides, and—if inoculated with malaria—tonics, cod-liver oil and malt, and cardiac stimulants during rigors. The number of patients inoculated with malaria was 263, but eighteen of these did not develop the disease, either because they were immune, or there was intercurrent disease and death, or a sudden lowering of vitality necessitated the administration of quinine before the onset of rigors. Of the 245 who had a first attack of malaria, sixty-one were inoculated for a second, but only in forty-nine cases was success achieved. Indeed, seventy inoculations were required to produce these forty-nine second attacks. A third attack was induced—but again with difficulty—in nine patients, while nine others proved refractory. The total number of inoculations was 397, of which 277 were intramuscular, thirty-eight intravenous, forty-one subcutaneous, and forty-one by mosquito, these last being especially useful in overcoming the resistance offered to the production of a second attack.

In the first attack 100 patients had seven to nine rigors, eighty-six had less than seven, and fifty-nine had more than nine, four rigors being the minimum likely to lead

to good results. The average number of rigors for the 245 first attacks was 7.5, and all but thirteen of these attacks were terminated by quinine. On the other hand, thirty-three of the forty-nine second attacks, and six out of the nine third attacks ceased spontaneously, and consequently the average number of rigors fell to 5.1 and 4.3 respectively.

In addition to inoculation with malaria, ultra-violet light, either alone or combined with auto-haemo-injections, was given to thirty-four patients, while forty-three had tryparsamide. To seventy-two cases one or more of the following were also given: bismotab, bivitol, bisglucol, iodo-bismuthate of quinine, stovarsol, sodium stovarsol, and acetyl-arsan.

CLINICAL RESULTS

Except for one patient with tabes, two with meningo-vascular syphilis who were discharged after intensive antisyphilitic treatment, and five recent admissions, all the non-malarialized patients are now dead, the majority having died within two years of admission. A large number of the malaria cases, however, are still in hospital; 30 per cent. have been discharged or transferred improved (some of these relapsing after a variable number of years), and of the 112 patients who died nineteen lived over three years. From a recent follow-up of old discharges these facts emerge. Of the 1923 admissions alone, thirty-six patients were treated by malaria; in 1933, ten years later, six were known to be at home (five being in very fair health) and five were still alive here. Of the 1924-7 group eighty-three had malaria; in 1933 twelve were known to be at home and fourteen were still alive in hospital (here or elsewhere), while seven more had been discharged but lost sight of. In the 1928-30 group forty-seven had malaria; twelve of these are now at home, eleven more are alive here, and six are untraced.

GENERAL OBSERVATIONS

That these results are not entirely due to malaria having been given only to early and hopeful cases is shown by the fact that of the 120 patients admitted in a bed-ridden condition no fewer than fifty-six had malaria, six being subsequently discharged, and eight more being still alive here, some after many years. With regard to habits as an indication of the stage of the disease, it may be mentioned that of the 207 patients who were admitted wet and dirty, malaria was given to 119, and as a result fifty-four became clean.

A renewal of malarial treatment in unimproved cases seems justified, for we have had seven patients who showed no benefit from the first attack and yet were discharged after the second. With regard to the addition of arsenical and bismuth preparations to malarial therapy the tables will show that we have had excellent results from malaria alone, but it would appear that these adjuvants rather hasten the clinical improvement as well as the serological amelioration. There are now sixty-four patients remaining in hospital (fifty-eight having had malaria), but only three are bed-ridden, five only are wet and dirty, and three have good prospects of an early discharge. The others are, for the most part, bodily fit and able to do physical work.

SEROLOGICAL CHANGES

As the majority of our long-treated cases examined serologically have naturally been drawn from those remaining in hospital—and therefore unimproved—a glance at the tables will show once more how little serological changes and clinical improvement go hand in hand. It will also be apparent that great improvement is often found in the fluid and blood reactions, but that this is most marked many years after the conclusion of the malarial treatment. Completely negative fluids, moreover, have been obtained by means of malaria alone. The specific tests for syphilis change more readily in the fluid than in the blood (sometimes relapsing later), the flocculation tests being more sensitive, and therefore more refractory after treatment, than the Wassermann. After the sixth year there is little likelihood of a Lange of 4 or 5 being found; while few cases show any abnormal cell count; the globulin also is negative by this time in the majority of cases.

CONCLUSIONS

Malarial therapy undoubtedly improves the bodily health. It prolongs life to a marked degree in some 35 per cent. of cases, and it has a beneficial effect upon the patient's habits and cleanliness. In about 18 to 20 per cent. of the patients it produces a clinical improvement that, as far as can be said at present, is likely to last many years, and often allows of a resumption of healthy and useful home life.

We are indebted to the medical superintendent, Dr. F. M. Rodgers, for permission to publish these results.

Clinical Memoranda

ACUTE THYROIDITIS FOLLOWING TEETH EXTRACTION

Acute thyroiditis is a sufficiently rare and interesting condition for this case to be worth reporting. It occurred in the practice of Dr. Andrew Simpson, Hawick, for whom I was acting as a locumtenent.

The patient, a woman aged 24, was a strong and, previously, healthy domestic servant. On August 26th, 1933, under local anaesthesia, Mr. G. Wallace Dunlop extracted seven teeth, involving the upper and lower jaws on each side. Two days later she stated that she felt discomfort in both sides of her neck, and on August 31st she first noticed pain and swelling in the region of the left lobe of the thyroid. I saw her for the first time on September 2nd. She had kept at her work, but was feeling very weak. Her temperature was 101° F. and her pulse 126; respirations were normal in rate and unembarrassed. The appearance of the gums was satisfactory. There was a hard, tense, and very tender swelling, which moved on swallowing, and was confined to, and conformed to the shape and relations of, the left lobe of the thyroid gland. The right lobe and isthmus, and the cervical lymphatic glands, were unaffected. She was confined to bed, kept on light diet, and given an aperient; ichthyol and glycerin dressings were applied. On September 3rd the temperature was 98.4° F. and pulse 78; she felt better, but the local condition appeared unaltered. The following day the temperature was 99° F., pulse 84; the local condition was still unaltered. By September 6th the morning and evening temperatures were keeping normal; the swelling was confined to the left lobe of the thyroid, but was less tense, and much less tender. Thereafter the patient made steady progress, and when last seen on October 12th, after a holiday, there was a little generalized enlargement of the whole thyroid gland, but no relative hardness or other abnormality of the left lobe.

The onset of acute thyroiditis so soon after teeth extraction can scarcely be dismissed as a coincidence, and I suggest that the infection was blood-borne from the gums, the patient's general resistance being lowered by continuing at work when she should have rested. The absence of any glandular swelling seems to rule out the possibility of the infection being by the lymph stream. The fact that the inflammation settled without any surgical intervention is surely another tribute to the very rich vascular supply to the thyroid gland.

Glasgow.

INTESTINAL OBSTRUCTION: PELVIC HAEMATOCELE

I have asked two gynaecologists whether they have ever come across a case of intestinal obstruction caused by a pelvic haematocoele. As their answers have been in the negative the following case may be worthy of publication.

The patient was an Indian Tamil, aged about 35, and an estate labourer. Previous history revealed that her first pregnancy had terminated in premature labour. She had two children, however, aged 10 and 8 years respectively, and since their births the menses had been regular though scanty. She had had no fainting fits.

History of the Attack.—Menstrual period began on May 13th and lasted one day, the fluid being slightly darker than usual. On May 14th the patient vomited three times, and on the following day she was constipated, had pain in the umbilical and hypogastric regions, and vomited again. On May 16th the morning temperature was 99.2°, pulse 110, with tympanites, tenderness, and slight rigidity; the evening temperature was 99.4°, pulse 118, with increased rigidity and

severe pain on the right of the umbilicus. The patient vomited once—gastric contents only.

She was seen at 6 p.m. on May 16th, when the pulse was 134, and outlines of distended intestine were visible. No flatus had been passed since the onset of the attack. Her condition appeared too low for operation, which, however, she declined. She was placed in Fowler's position and given glucose-sodium bicarbonate in sips, and morphine 1/4 grain. On May 17th the morning temperature was 99° and pulse 120; the tongue was moist, and there had been no vomiting during the night. The patient consented to an operation, the chances of recovery from which seemed more hopeful. Six ounces of hypertonic saline (10 per cent.) were given intravenously, the patient complaining of substernal oppression, a general burning sensation, and severe colicky pains without relief.

Operation.—A right rectus subumbilical incision was made. The omentum, which was thickened and adherent to the peritoneum, was incised and a cystic swelling exposed, which was emptied of a pint of dark clots and drained, there being no bleeding. As the ileum was friable and adherent to the cyst wall, no attempt was made to tackle the obstruction; no foetus was found on cursory examination of the contents. Within an hour flatus and faeces were passed. On the twenty-fifth day the placenta, an ovoid flattened mass (size 2 in. x 1 in. x 3/4 in.), was expelled through the wound.

Haputale, Ceylon.

A CASE OF PARALDEHYDE POISONING

Paraldehyde is a sedative and hypnotic drug used most often in mental cases and in the insomnia of alcoholic patients. The therapeutic dose is 30 to 120 minims, and the drug is not a scheduled poison, although fatal cases have been recorded after doses of one, two,¹ three,² and four³ ounces.

The patient, a man aged 71, was admitted to the Stepping Hill Hospital on November 28th, 1933, at 11 a.m., in a state of profound unconsciousness. The temperature was subnormal, and the pulse rate 130. The conjunctival and pharyngeal reflexes were absent, and the odour of paraldehyde could be detected in the breath and at a considerable distance from the patient's bedside. The patient's own doctor informed me that he had prescribed a mixture containing four drachms of paraldehyde in four ounces of water, with instructions that the patient should take half of the contents of the bottle at bedtime on November 27th as a sleeping draught. Unfortunately the chemist made the error of filling the bottle with pure paraldehyde, so that two ounces of the drug were taken. The stomach was washed out by means of a weak solution of sodium bicarbonate, but there was no trace of paraldehyde in the wash-out. Strychnine, coramine, and pituitrin were administered. One pint of saline was given intravenously. As the breathing was very shallow, artificial respiration was applied at intervals, and pure oxygen and a mixture of oxygen and CO₂ were administered alternately. A gag was inserted into the mouth to aid the excretion of the paraldehyde; three ounces of black coffee were given per rectum. There was retention of urine, and twenty-four ounces were withdrawn from the bladder. The pharyngeal and conjunctival reflexes did not return until 7 p.m. the same day, and complete consciousness was not regained until 7 a.m. the following day.

The above case again demonstrates the commonly observed fact that poisoning by this drug is usually the result of an accident; its nauseating odour and taste inhibit its use as a suicidal agent. The notes are also interesting because of the recovery of the patient after a dose of two ounces.

Reviews

PUBLIC HEALTH TEACHING

The Heath Clark Lectures given last year in the London School of Hygiene and Tropical Medicine by Professor PRAUSNITZ of Breslau have now appeared in book form.¹ The subject dealt with is the teaching of preventive medicine in Europe. In an introductory chapter the view is put forward that the State, having an interest in developing preventive medicine, should do all in its power to advance that object by founding and maintaining adequate institutes of hygiene. The author states that such institutes were at first attached to the universities, but that these educational bodies proved to be too engrossed in research and the instruction of undergraduates to be able to deal in a competent manner with certain newer problems arising, such; for example, as post-graduate teaching and the training of subordinate lay personnel for public health work. It should, however, we think, be noted, so far as this country is concerned, that a number of our universities are now carrying on post-graduate teaching, and that those which have not opened their doors for the training of lay subordinates may possibly have refrained from doing so, not on account of any inability to cope with the task, but because the standard appropriate to such instruction did not appear to them to be compatible with the higher learning. In any event, as the author says, a new type of institute of hygiene has lately come into being, usually under State control, and in many cases erected with the aid of funds supplied by the Rockefeller Foundation. One such has been established in this country, the London School of Hygiene and Tropical Medicine, which, although on the new model, retains the academic connexion, being happily affiliated to the University of London.

The author classes practical work in prevention in two divisions. One of these comprises the environmental services, such as water supply and food control, which from the outset have provided a field for central and local government activity. The second embraces the social services, which, among other objects, safeguard the mother and child, and have brought the health visitor upon the scene. With regard to the last-named official, medical officers will learn with mingled feelings that "in preventive medicine work she is just as necessary as the chief and his medically trained assistants, whose work she supplements." The introduction concludes with a survey of the development of schools of social service, in the course of which the significant fact emerges that as the quantity of trained social workers increases their quality falls off.

In the body of the work accounts are presented of the teaching of preventive medicine in France, Germany, Great Britain, Poland, Hungary, Czechoslovakia, Yugoslavia, Spain, Greece, and Russia. In the chapter on Great Britain the author gives a summary of English sanitary administration, describes the move of the Society of Medical Officers of Health to interest teaching bodies in prevention, and quotes in full the rules of the General Medical Council for degrees and diplomas in sanitary science. Proceeding next, however, to deal with the teaching of medical graduates for these qualifications he centres his attention on the London School of Hygiene and Tropical Medicine, dismissing with a casual reference "a certain number of universities and other institutions in the United Kingdom" which are also giving training. While the London School more than merits every tittle of praise which the author bestows, we cannot but think

that the exclusive reference to it gives a quite inadequate portrayal of what is being done throughout Britain generally for post-graduate public health teaching.

The chapters dealing with the remaining countries present a variety of health institutions, whose equipment and service reflect the stage of sanitary progress in each community. The activities described range from the control of sera in several State institutes to the sewing class for women students in the peasants' university at Zagreb. It appears that in France health visitors who have received a general training are styled "polyvalent." In his closing chapter, which is devoted to the work of the League of Nations, the author quotes the conclusions of the Dresden conference on schools of hygiene. It may be noted that the second of these conclusions favours the closest possible link between the universities and the schools of hygiene. The book in general may be commended to the perusal of public health teachers. It will provide them with a stimulus, challenge, or warning, according to their point of view.

FRENCH PAEDIATRICS

Under the general editorship of Professor P. NOBÉCOURT and Dr. LÉON BABONNEIX a group of about eighty paediatricians and specialists dealing with related subjects have planned a large treatise on Diseases of Children in five volumes, the first three² of which have now appeared. Magnificently bound, printed on good paper, with copious illustrations, and with a table of contents for the whole five parts amounting to nearly sixty pages, this work would seem to be a very worthy achievement by that school of paediatrics of which so many of the founders look down from their photographs at the top of the pages of the Introduction. This, consisting of over forty pages, from the able pen of Dr. Babonneix, is in effect a statement of the paediatrician's creed with an historic background, an exposition of the methods employed, and a summary of the preventive measures now available. The main body of the first volume opens with a section on growth and its disorders, leading on to a block of two hundred pages on "disorders of nutrition," which is taken to include such diverse subjects as marasmus and chronic articular rheumatism, both of which are more commonly regarded in this country as having an infectious origin. The bulk of the rest of this volume is concerned with deficiency diseases and with diseases of the endocrine glands. The former, besides containing a surprising section on disorders associated with deficiency of cellulose in the diet, is mostly written by Dr. C. Lesné with the collaboration of Dr. R. Clément and Mlle G. Dreyfus-Sée, and is of the high standard to be expected from this author, whose wide outlook is particularly valuable in view of the international nature of vitamin research. Dr. H. Janet has been responsible for most of the chapter on the endocrine glands, a subject giving full scope for that power of clinical exposition so essentially associated with French medicine. The second volume is largely devoted to a consideration of the infectious diseases, and rheumatism again crops up in its acute forms. Syphilis is well covered, as might be expected, by a series of articles mostly by Dr. M. Pehu of Lyons, while Professor R. Debré and Dr. M. Lelong contribute a well-balanced section on the general aspects of tuberculosis in childhood. A comparatively short section (in contrast to the space devoted to other subjects) on disorders of the blood and blood-forming organs concludes this volume, and in view of the advances of the last few years this

¹ *The Teaching of Preventive Medicine in Europe*. By C. Prausnitz, M.D. London: H. Milford, Oxford University Press. (Pp. 180; 37 figures. 10s. 6d. net.)

² *Traité de Médecine des Enfants*. Publiée sous la direction de P. Nobécourt et L. Babonneix. Secrétaires de la rédaction: J. Cathala et J. Hutinel. Tomes I, 2, et 3. Paris: Masson et Cie. 1934. (Pp. 998, 958, and 1,086; illustrated. Broché 150 fr., relié 170 fr. each.)

part of the book is somewhat disappointing. Volume iii is concerned with disorders of the circulatory system, the respiratory system, and the alimentary system. A disappointing opening section on congenital heart lesions, in which congenital syphilis is considered as an important indirect aetiological factor, is more than compensated for by a stimulating section on intrathoracic tuberculosis in children, a subject which of late has been brilliantly studied in Paris. The radiographic illustrations are well chosen and excellently reproduced. Throughout all three volumes there runs a clarity of expression and a note of dogmatism which makes for clear teaching. Anyone wishing to discover exactly what is thought in France on diseases of children will easily find it, even if sometimes it is in disagreement with views held elsewhere.

This same Gallie spirit is exhibited in a small book on *Infantilism*, by Dr. E. Apert (another of the contributors to the new treatise), which Dr. R. W. B. Ellis has recently translated and adapted.³ This is a simple, well-written monograph, dealing with the principal types of infantilism, a term apparently introduced more than sixty years ago by Laségue. The illustrations are well chosen, and Dr. Ellis has added a brief but useful summary of recent work on renal infantilism and coeliac disease, which enhances the value of the book.

EVOLUTION OF THE VERTEBRAL COLUMN

The Evolution of the Vertebral Column,⁴ a contribution to the study of vertebrate phylogeny, by the late H. F. Gadow, F.R.S., has been edited by Dr. J. F. Gaskell and Mr. H. L. H. H. Green. The frontispiece of this work will recall to many graduates of the University of Cambridge and to members of the Anatomical Society the features of a pleasant and witty gentleman who spoke English fluently but with a pronounced German accent. His accent was not the only thing Dr. Gadow brought with him from Germany: he brought with him the traditions, aims, and ideals of the great German school of morphologists. He was a pupil of that prince of morphologists, Carl Gegenbaur, a potent force in the seventies of last century, when Gadow was his pupil, but now little more than a name to the rising school of zoologists. Gegenbaur's impress on Gadow was deep and permanent: he devoted his life to the elucidation of morphological problems taken over by him from his master. A sentence from the present work will illustrate how Gegenbaur's influence permeated his outlook:

"In 1879 we, Gegenbaur's staff and special pupils, approved of the master's sneering remark that, according to Claus, the pelvis of the eel-shaped *Perennibranchiatus* was so 'rudimentär' and placed so far back 'because it had got out of control.' Intercalation of vertebrae was not allowed, and tailward migration of the pelvis was at least disapproved for obvious reasons."

Gadow absorbed the enthusiasms of the morphological school in which he was trained, and in these pages mentions lovingly such names as Fries, Van Wijhe, and Fürbringer—familiar names half a century ago, now, alas! rarely mentioned. How elaborately research was done in these halcyon days is illustrated by another remark made in this book:

"He [Fürbringer] crowned his researches by his contribution to Gegenbaur's *Festschrift* under the title 'Ueber die Spino-occipitalen Nerven der Selachier und Holocephalen und ihre vergleichende Anatomie.' This monumental work of 440 quarto pages and eight double plates contains a well-nigh exhaustive morphology of the whole post-vagal and cervical regions from lampreys to the mammalia."

³ *Infantilism*. By E. Apert. Translated by R. W. B. Ellis, M.D. London: Martin Hopkinson Ltd. 1933. (Pp. 117; 25 figures. 7s. 6d. net.)

⁴ *The Evolution of the Vertebral Column*. By H. F. Gadow, M.A., Ph.D., F.R.S. Edited by J. F. Gaskell and H. L. H. H. Green. Cambridge: The University Press. 1933. (Pp. xiv + 356; 123 figures. 25s. net.)

This sentence illustrates the enthusiasm of the school in which Gadow was trained. Steeped in the traditions of the German morphologists, Gadow was given opportunities to develop his ideas in the University of Cambridge. He died in Cambridge on May 16th, 1928, aged 73. During his lifetime he read contributions to learned societies on many anatomical problems. The subject to which he devoted his chief attention—namely, the various forms assumed by the backbone, not only in all living vertebrate animals, but in extinct species of fish, amphibia, and reptiles—he said little about. After his death were found the materials he had collected to permit him to write a full history of the vertebral column. Seeing that the vertebral column has been in process of evolution for hundreds of millions of years and is the chief structure of a kingdom of animals, and that it was the main subject of his investigation for forty years, we cannot grudge the 356 pages needed for his printed text. Fürbringer required 440 quarto pages to do justice to the morphology of the atlas and axis!

In the course of evolution some structures have become more complicated, others have become simpler. A human vertebra in its adult state is a single bone; in certain early fishes a vertebra is represented by ten separate pieces. It would take us too far afield to attempt to outline the contributions Dr. Gadow has made to our knowledge of the evolutionary history of the vertebral column. Suffice it to say that anatomists who are seeking to unravel the history of all lines of vertebrate animals will be indebted to the editors for the labour spent in preparing Dr. Gadow's manuscript for publication, and particularly to Mrs. Gadow for the assistance she has rendered them. Especially are we glad to note the gracious and true things Dr. Gadow wrote concerning the zoological discoveries of his gifted colleague the late W. H. Gaskell. We find only one serious omission: there is no biographical introduction. Dr. Gadow richly deserved one.

EXTRACTION OF TEETH

The third edition of Mr. FRANK COLEMAN's *Extraction of Teeth*⁵ comes opportunely at a time when the "surgical extraction of teeth" is being widely advocated. Turning at once to the chapter on "Surgical Removal of Teeth," one reads: "The more skilled a practitioner has become in the use of tooth forceps, the less need will he have for resorting to other methods for the removal of teeth"; and one finds no mention of curing the sockets, or of trimming off alveolar bone to expedite healing. The chisel and mallet, and "surgical" instruments other than forceps, find their chief use in the removal of impacted teeth and buried roots. This chapter ("Technique of Surgical Removal of Teeth") is an excellent, though short, summary of a much debated subject.

The main body of the book deals, in three well-balanced chapters, with the technique of extraction; the difficulties, complications, and sequels of extraction; and extraction under anaesthesia. The last of these chapters calls for special mention, particularly the part devoted to injection anaesthesia; Mr. Coleman's wide knowledge of pharmacology has enabled him to write with authority, and no detail that makes for success is too trivial for mention. Reading of the dangers of extraction, one feels almost a sense of disappointment that he has no hope for the haemophilic: "the rule that the extraction of teeth must never be undertaken in haemophilic patients is one that can rarely have any exceptions." (Bowdler Henry records a case in which coagulation of the periodontal tissues by

⁵ *Extraction of Teeth*. By F. Coleman, M.C., L.R.C.P., M.R.C.S., L.D.S. Third edition. London: H. K. Lewis and Co. Ltd. 1933. (Pp. vii + 232; 131 figures. 12s. 6d. net.)

diathermy was followed by successful extraction.) The first chapter—on technique of extraction—leaves no doubt in the reader's mind of the value of forceps and elevators (or of the more refined instruments known as exolevers) in the routine extraction of teeth. One may, perhaps, criticize the author for his rather cryptic reference to the status lymphaticus—is it in his opinion a clinical entity? The illustrations are numerous, well chosen, and very clearly explain the text. It is a book that will find a wide welcome.

SEX DIFFICULTIES IN THE MALE

The book by Mr. KENNETH WALKER now published under the title *Sex Difficulties in the Male*⁶ is really a second edition of *Male Disorders of Sex*, which appeared in 1930. The new title is obviously the more appropriate, because a large portion of the book is given up to discussion of minor derangements of sexual function which are better described as "difficulties" than as "disorders." All that need be said in recommendation of the work in its present form is that it is even more readable, and likely to be even more useful, than the first edition. It contains a new chapter on the subject of difficulties encountered in marriage, written in language that is as little technical as possible for the sake of non-medical readers. Mr. Walker knows how to make a book interesting. He knows also how to give advice without moralizing, and without being pontifical. Generally the advice seems excellent, and even when it does not fit in with our preconceived ideas, we must admit that it is generous and full of common sense.

Notes on Books

The art of "dressing" for an ophthalmic surgeon, whether that be done by a nurse, student, house-surgeon, or a general practitioner, requires certain specialized knowledge which is not ordinarily acquired during the regular training. Mr. HUGH JONES has sought to assist in filling this lacuna by the preparation of a little book giving *Practical Points in Eye Surgery and Dressing*.⁷ He believes that the study of this book and the instructions given therein will prevent harmful first aid, and ensure helpful preparation for operations. Wrong preliminary treatment of urgent cases in the absence of the surgeon (for example, the use of atropine instead of eserine) may have disastrous results, while a *laissez faire* policy may sacrifice the only chance of saving an eye. The book is complete in a couple of dozen pages, with an envelope in the cover with charts setting out the salient points to be observed. Notes are given on the methodical examination of the eye, on the instruments and drugs needed in an out-patient department, and on the sterilization of eyedrops; the handling of urgent cases, and of injuries; and finally, there is a chapter on preparation for operation, the examination of the general condition of the patient, and in particular search for foci of possible infection, the preparation of the lids and conjunctiva, and of the instrument, and finally on after-care. The writing is terse, the instructions clear and practical. The book should be of value to students on the threshold of eye work. Even in places where there are variations from the practice adopted by Mr. Hugh Jones, his notes will be of interest, for these differences will be sure to stimulate inquiry and thought.

The *Transactions of the Third International Paediatric Congress*, which was held in London last July, have now been published as a special number of the *Acta Paediatrica*.⁸ The main discussions, on allergy and on

the prophylaxis of milk-borne diseases, have already been reported in these columns. The full reports account for nearly half of the total pages devoted to the scientific proceedings, the remainder being occupied by the independent communications, which have a very wide range, and, with the subsequent discussions, are printed in one of the four official languages of the congress—English, French, German, and Italian. The printers and publishers of the *Acta Paediatrica* are used to such polyglot work, and the general production is very good for this type of publication. A short subject index—all that has been possible in view of the complicated nature of the volume—has been provided, and should enable those interested in a particular malady to find what was said about it. The editors responsible for the compilation of this special number are Dr. Robert Hutchison and Dr. Alan Moncrieff.

The *Pharmaceutical Pocket Book* first appeared under the editorship of Mr. John Humphrey in 1906. After passing through several editions the task of revision was entrusted by the Council of the Pharmacological Society to its Science Committee in 1923, and the eleventh edition, which appeared two years later, was noticed in these columns on June 13th, 1925. A new edition has now been produced under the supervision of the Codex Committee, edited by Mr. C. W. MAPLETHORPE. The contents show evidence of thorough revision, and the work in its new form should prove invaluable as a reference book for practising pharmacists. It also contains a great deal of information of practical use to general practitioners, medical officers of health, analytical chemists, and veterinary surgeons. Copies may be obtained from the publications manager, Pharmaceutical Press, 23, Bloomsbury Square, W.1 (5s. 6d. post free).

Preparations and Appliances

A PROTECTIVE MASK FOR USE AFTER OPERATIONS ON THE EYE

Lieut.-Colonel H. KIRKPATRICK, M.B., I.M.S. (ret.), London, W., writes:

Accidental injury of an eye whilst convalescing from an intraocular operation is an unfortunate complication which is sometimes met with. A protective shield should be (1) light and strong, (2) comfortable to wear, and (3) so constructed that it cannot be displaced by any movement of the patient's head on the pillow. Until recently, in my experience, no available device entirely fulfilled these requirements; but Messrs. Clement Clarke, 16, Wigmore Street, have now made for me a mask which appears to be wholly satisfactory. The

material is a composition resembling celluloid, and the mask is shaped to fit closely the orbital margins and superciliary ridges. The material is sufficiently rigid to afford protection and is yet sufficiently elastic to allow the mask to fit nearly every case. If necessary, however, it can be remoulded for an exceptional patient by softening it in hot water.

There is a bulging prominence in the shield over each eye, and the centres of these prominences are removed to allow proper ventilation. The mask can be used over a dressing instead of a bandage and is tied in position by two tapes which pass round the head, one above the ears and the other below. The shield will serve as a comfortable protective shade after the dressings have been removed. A separate shield for each eye can be used if desired, but a mask which covers both eyes is usually to be preferred.

HOUSING AND RESPIRATORY DISEASE

A GLASGOW INQUIRY

Dr. C. M. Smith in a recent admirable report¹ discusses his study of the comparative incidence of respiratory disease in a slum and in a rehousing area of the city of Glasgow. The weight of major respiratory disease as a cause of death is often sufficient to affect the total death rates of communities, while minor respiratory diseases, together with influenza, may prove an outstanding cause of morbidity, having been responsible, as was shown lately in connexion with national insurance, for nearly 40 per cent. of incapacity leading to claims for sickness benefit. Information, therefore, such as this study supplies, on the incidence of respiratory disease, serves a most useful purpose, in so far as it may throw light on the manner in which transmission of such disease occurs and so point to measures fitted to obstruct or bar the path of infection.

The report indicates that the inhabitants of the slum and the rehousing area in question numbered about 1,000 in each case, making 2,000 in all. They were observed by means of a weekly house-to-house visitation over a period of one year, beginning in mid-September, 1928. In the two areas combined there were fifty-five cases of pneumonia, of which twelve proved fatal. These figures represent an incidence rate of 27.3 per thousand, a case mortality rate of 21.82 per cent., and a death rate of 5.96 per thousand. Compared with Glasgow as a whole this death rate is high, but the case mortality rate is not, and the figures suggest to the author's mind the general implication that, in poor areas a high pneumonia death rate may simply mean a high incidence of the disease, and not (as might otherwise be surmised) a high case mortality rate resulting from neglect, malnutrition, or similar causes.

SLUM AND REHOUSING AREAS COMPARED

Comparing now the two areas, the slum and the rehousing area, with one another as regards the respective incidence upon them of all acute respiratory diseases, from conditions so mild that the sick person did not take to bed up to pleurisy and pneumonia, and employing the average number of days in bed per head as the measure of severity, the author works out for the slum area 2.104 days in bed per head, and for the superior rehousing area 2.425 days. That is to say, the slum people had less illness than their betters, reckoned by days in bed. This is a distinct inversion of what might naturally have been expected, and the author modestly suggests three reasons 'why his figures' should be accepted with caution.

First, the slum population included a considerable foreign element, consisting of Jews and Lithuanians, who were not only more in employment but also fed themselves on more hygienic lines than the native Scot. When these aliens, whose record of respiratory disease was for the reasons suggested low, are deducted from the total, the days in bed for the slum inhabitants rise to 2.229, higher than the previous figure but still below that for the rehousing area.

Secondly, the slum people, through rooted suspicion or owing to unfamiliarity with procedure, were often reluctant to co-operate with the officials who made the weekly visits, and, therefore, apt to suppress data which should have come to light. The rehoused people, on the other hand, accustomed to periodical supervision by health visitors and others, were ready to tell everything. As

a result, the figure for the slum does not quite represent the facts, stating fewer days in bed than should have been recorded.

EFFECTIVE OVERCROWDING

The author's final reason for discounting, to some extent, the figures under discussion relates to the question of formal as distinguished from effective overcrowding, formal overcrowding being determined by the number of persons per apartment in the house and effective overcrowding by the number of persons per room used for sleeping. On the formal standard that three persons per apartment, each child being counted as one person, constitutes overcrowding, 43.4 per cent. of the slum dwellers were overcrowded and only 8.5 per cent. of the rehoused people. But on the effective standard of more than three persons per room used for sleeping, 42.8 per cent. of the slum dwellers were overcrowded and 35.3 per cent. of the rehoused. The slum dwellers on the effective standard show up rather better than on the formal standard, the rehoused population perceptibly worse. The people still in the slums, presumably having no option, used all the rooms in the house for sleeping: the former slum dwellers, now rehoused, although they had several rooms at disposal, left one or more unoccupied. Owing to these ill-advised arrangements, they were, as regards effective overcrowding, little better off than the slum dwellers, and since in crowded sleeping quarters respiratory infection is quickly spread, their experience of respiratory disease instead of being relatively light was heavy, and by the test of number of days in bed actually the worse of the two.

It is, of course, a regrettable circumstance that rehoused slum dwellers in Glasgow or anywhere else should fail to turn their more spacious dwellings to better account in this particular. It need not, however, cause surprise or be unduly reprobated. *Caelum non animam mutant*, when transported to the fresh environment. They carry with them to their new quarters the outlook and the habit of life to which they were previously accustomed, and, crowding together into one room at night as in the days of old, seek warmth, which they probably find, but at the same time expose themselves and their children to certain risks.

SUMMATION OF RESIDUES

In the case of respiratory infection or any disease the virus of which is located in the respiratory tract the spray repeatedly launched in speaking, coughing, or sneezing from the mouth or nose of sick persons or carriers is charged with the specific contagium, which thus hangs in the air and may ultimately lodge in the respiratory tract of another person. Whether or not the other person actually becomes infected depends upon the speculative factor which S. F. Dudley has called the velocity of infection. If the first charge of virus which lodges fails to infect, a second or third or fourth may succeed. The summation of residues tells in the end. But if the individual charge is weak it is only by a succession of charges that infection can ever occur, and a succession of charges can only lodge if the person at risk remains within range. The range of the virus in the air is short, probably only a few feet, and a person at risk, moving about by day in rooms or offices or elsewhere, may often enough unwittingly receive a single charge from an unrecognized source—namely, a sick person or carrier—but move away out of range before a second charge can reach him. At night, however, when in bed, he is immobilized for a matter of hours, and if by chance he is sleeping in a room with other persons who include in their number a sick person or a carrier of a respiratory infection he

¹ Medical Research Council, Special Report Series No. 192. H.M. Stationery Office. 1934. (9d.)

remains continuously within range all night and may so receive that summation of charges which culminates in his infection followed by an attack of illness.

NUMBER OF ROOMS

The range of the air-borne virus is short, as already noted, and a measure so apparently trivial as the spacing-out of soldiers in barracks or boys in dormitories has been found useful for its control. The corresponding method of spacing-out in a working-class dwelling would be to employ all the rooms for sleeping, so reducing to the minimum the number of sleepers per room. For such an arrangement, or rearrangement, a certain number of rooms is necessary, and it is probably not too much to say that for the control of respiratory infection the number of rooms matters more than cubic space or even floor area. The family house of three rooms which allows of the separation of the sexes at night will, if all the rooms are utilized—which local authorities in their rehousing areas are usually in a position to enforce—provide also a valuable security against the air-borne respiratory viruses. It is thus worthy to be commended alike on social and hygienic grounds. While the social evil is the graver and calls more urgently for remedy, it is, nevertheless, satisfactory to reflect that progress towards its amelioration will almost inevitably confer a coincidental degree of protection against the spread of respiratory disease.

STERILIZATION IN GERMANY

In view of the findings of the Brock report,¹ the opinion of a leading German psychiatrist² on the German Statute for the Prevention of Hereditary Disease is particularly interesting. The Act, which came into force at the beginning of this year, provides that a person may be sterilized when it is highly probable (*mit grosser Wahrscheinlichkeit*) on scientific grounds that his progeny will suffer from severe hereditary physical or mental illness.

The legislator, says Professor Gaupp, has placed an implicit and perhaps not an entirely deserved faith in the ability of medical men to determine this question of probability. Moreover, the phrase is a very ambiguous one. An event can hardly be called highly probable unless statistics show that it happens, on an average, in 50 per cent. of cases, and there can be few cases in which the most experienced medical geneticist will declare that the chances are even that if a certain person has a child it will be tainted. Much work is being done to define the probability of transmission of defects. Ernst Rüdin, in his work on the empirical prognosis of heredity, published last year, states that if a parent has hereditary chorea 50 per cent. of the offspring will be diseased. If one parent is a manic-depressive one-third of the children are likely to be affected and another third to show signs of constitutional disease, but if both parents suffer then 62.5 per cent. on an average are likely to inherit the specific psychosis, and all the remainder will probably be mentally abnormal. Unfortunately this is just the condition which is most difficult to deal with from a eugenic point of view. Manic-depressives are often very gifted and creative people, who in their sane periods contribute notably to the culture of the world; and to go too far in sterilizing parents of this class might seriously impoverish society. Bumke once said that it would have the effect of blotting all the feeling, warmth, and beauty out of existence, and of leaving nothing but a couple of miserable bureaucrats and a few schizoids. Professor Gaupp suggests that sufferers from mild and infrequent attacks, and those who first show the disease at an

advanced age, ought not to be sterilized if their spouses come from quite healthy stock. For violent patients, on the other hand, who have undergone severe and repeated attacks since puberty, he considers sterilization advisable if there are indications that the spouse has a hereditary taint. The decision, he says emphatically, should only be taken by experienced mental specialists after the most careful investigation.

The naïve expectation is often expressed in Germany that its new and determined Government will succeed in eradicating schizophrenia in two generations. The trouble is, he explains, that it is not the parents of schizophrenes who are afflicted with schizophrenia, but their uncles, aunts, and cousins, and under the new law it is only possible to sterilize the patient, not his relations. When one parent is schizophrenic the chances of any particular child inheriting the psychosis are only between 7 and 10 per cent.; when both parents are afflicted they are about even. It may be true that the offspring of schizophrenes often show definite psychic abnormalities of other kinds, but an inheritance probability of 2 to 7 per cent., the figures given by Rüdin, will hardly satisfy the terms of the Act. Professor Gaupp thinks that the law will best be applied if the parents of young schizophrenes will acquiesce in their sterilization before they are sent home improved from the mental hospital. As these patients usually make bad parents, the sociological and the eugenic considerations are in harmony.

Although it may be possible in theory to distinguish true hereditary epilepsy from the numerous acquired conditions that closely imitate it, certainly is, he says, very difficult in clinical practice, and can only be attained by a full history since birth and a thorough examination by a skilled and experienced neurologist. According to Rüdin, about 10 per cent. of the children of an epileptic are affected, but the disease is much rarer in the grandchildren. Mental deficiency is a different matter from mental disorder, for it is fairly well established that hereditary mental defectives hardly ever produce ordinarily healthy offspring. Moreover, they tend to mate together, so that the influence of a sound partner is absent. This is the class which has always seemed most fitted for sterilization. Here again, however, says Professor Gaupp, it is difficult to distinguish the true inherited condition from one produced by intrauterine or early trauma, but he suggests that if here and there, in the course of a nation-wide campaign, a mental defective is misdiagnosed as hereditary, it is a small price to pay, especially in view of the well-known incompetence of mental defectives as parents.

The author is wholeheartedly in favour of sterilizing the morally insane and defective, for he is convinced that they never produce socially valuable offspring. Inveterate alcoholics, he says, seem to come under the Act, as they often have a psychopathic heredity and are shockingly bad parents; but alcoholism as such has not been demonstrated with any certainty to be hereditary. Research may, suggests Professor Gaupp, succeed in proving that it is one symptom of a transmissible "*Verlustmutation*," or general tendency to addiction, the particular manifestation of which will be determined by factors affecting the individual. It is a grave responsibility to condemn patients to sterilization on a knowledge which is admittedly in its infancy. The medical profession must, Professor Gaupp concludes, sterilize only on the fullest and most cautious investigation, and in the meanwhile push on with the utmost energy their research into hereditary pathology.

A conference on *B. coli* infections will be held at Châtel-Guyon on September 23rd and 24th. It had been announced originally as arranged for May 20th and 21st, but this date was considered to be too near that of the congress on lymphatism, and so postponement was deemed advisable. The discussions will include the various infections and intoxications of intestinal origin. The general secretary of the conference is Dr. P. Balme, and inquiries should be addressed to him at the Société des Eaux Minérales, Châtel-Guyon, Puy-de-Dôme.

British Medical Journal

SATURDAY, MARCH 10th, 1934

MEDICAL RESEARCH COUNCIL

The death of Sir Walter Fletcher in June last year came as a profound shock to the medical profession. Sir Walter *was*, it was felt, the Medical Research Council, and his sudden severance from it has led his successor, Dr. Edward Mellanby, in presenting the annual report of the Council for 1932-3,¹ to reflect upon the organization of State assistance to medical science during the past thirty years. "The history of these developments," it is stated in the introduction, "lies largely within the period when Sir Walter Fletcher was taking the leading part in the initiation and guidance of policy to this end. The constitutional freedom, administrative effectiveness, and general good will which have been secured are in great measure the reward of his vision and the fruit of his labour." No more fitting tribute could be paid.

One of the terms of the National Health Insurance Act of 1911 was the establishment of a committee to administer a fund for medical research which was to be paid from the Exchequer at the rate of 1d. a year for every insured person in the United Kingdom. This yielded approximately £53,000 in the first year. In July, 1914, Walter Fletcher was appointed the first secretary to the Medical Research Committee, which came into being in 1913 as a result of the Act of 1911. Under the Ministry of Health Act of 1919 the general administrative control of this work was transferred from the Insurance Commissioners to the Privy Council, and the committee was succeeded by the Medical Research Council, incorporated by Royal Charter in 1920. At the same time its finances were put on an independent basis and the Treasury provision was raised to £125,000 a year, an amount which has since been increased. Within twenty years an effective monetary liaison has been established between Medicine and the State, while freedom to pursue an independent policy has been preserved. With the Department of Scientific and Industrial Research and the Agricultural Research Council the Medical Research Council constitutes a triad whose services cover the whole ground of science in its practical applications to the needs of the community.

It would be ungracious to belittle the financial aid given by the State, but we must remember that the politician does not usually see in the promotion of scientific research an effective remedy for a dwindling popularity with the electorate. He has therefore

often shown reluctance to divert to that end money which might appear to yield a quicker return of profits if applied to other spheres of activity. On the supposition that the concern of a democratic Government is for the greatest good of the greatest number, few would question that health of body and mind is as great a good as any. To secure and promote this health more money is needed for research, and there is no room for complacency with things as they are, notwithstanding the fact that they are considerably better than they were thirty years ago. In the report of the Medical Research Council for 1931-2 the need for clinical research was strongly urged, but, as we said at the time,² "there is a dearth of posts which could be filled by the many men who cannot, for economic reasons, fulfil their early promise in this line of work." The Council returns to this matter again in its present report, and notes with approval the increase in whole-time professorships in clinical medicine and surgery—a vindication of its "strong belief that a primary necessity in the situation is the establishment of a greater number of senior posts for whole-time work in research and higher teaching, such as will give a possibility of a satisfactory career in later life to young men who devote themselves to the scientific study of clinical problems." The permanent endowment last year by the Rockefeller Foundation of the post held by Sir Thomas Lewis, and the recent decision of the Beit trustees to release funds for the appointment of a senior research worker in clinical science, are welcome and generous moves in support of the Council's policy, a policy that needs all the financial endorsement it can get, whether from the State or from private benefactors. As another reflection of this policy we have greeted the appearance of the new journal, *Clinical Science*—new only in title and scope, for it is the direct successor of *Heart*, and continues under the able editorship of Sir Thomas Lewis.

In the twenty years since the formation of the original Medical Research Committee there have been widespread changes in the problems of disease. As a result of some unassignable cause certain diseases, formerly common, have become textbook curiosities. One of these is chlorosis; another is epidemic diarrhoea and vomiting of children, which played such havoc among infants in the summer of 1911 and in many earlier hot seasons. The incidence of other maladies has fallen as a consequence of the action of public health authorities and of better education, increased cleanliness, and the "conversion of the populace from drunkenness to sobriety," with a resulting diminution of cirrhosis of the liver and of mortality due to the overlaying of children. "There remains an important group in which the change is the direct result of new knowledge acquired by recent research: to this advance it may be confidently claimed that workers in this country—very many of them aided by the Council—have largely contributed." To illustrate this advance the report refers to certain of the diseases

¹ Report of the Medical Research Council for the Year 1932-3. H.M. Stationery Office. (2s. 6d. net.)

² *British Medical Journal*, 1933, i, 421.

chosen for investigation by the Committee in its first annual report published in 1915: tuberculosis, rickets, chronic arthritis, epidemic diarrhoea and vomiting, diabetes, oral sepsis, and status lymphaticus. Of these, rickets can now be controlled and cured (it is hardly necessary to remind readers of the *British Medical Journal* of the part played in this by Edward Mellanby); the major terrors of diabetes have been removed; the causes of dental and periodontal diseases are now better understood, and the practical application of May Mellanby's work may prove another cornerstone in preventive medicine; the prevention and treatment of tuberculosis, especially in the collapse therapy of pulmonary tuberculosis, has greatly advanced; status lymphaticus "has been shown to have no existence as a definite morbid state"; but chronic arthritis, unfortunately, still remains a problem.

Since 1915 medicine, aided as it has been by physiologists, biochemists, and bacteriologists, has advanced along such a wide front, consolidating its position with each advance, that to catalogue its achievements would exhaust the reader, and particularities tend to obscure the general issues. The Council makes a bold and interesting generalization when it says that just as the last century was distinguished for the discoveries which led to the germ theory of disease, so will the present century come to be known as the "age of development of knowledge of metabolic disease." The rapid extension of knowledge of the endocrine glands and of vitamins, with the identification and isolation of insulin, adrenaline, thyroxine, pituitrin, parathormone, suprarenal cortical extract, calciferol, ascorbic acid, etc., and the increased information concerning the effects of excess or deficiency of these particular chemical substances, have provided the physician with therapeutic weapons that can be directed at the cause of the disease rather than at symptoms. The elaboration and perfection of diagnostic methods; the discovery of new remedies; the facilitation of modern surgery by such measures as blood transfusion, the use of carbon dioxide and the barbitone derivatives and avertin in anaesthesia, and the employment of x rays and radium in the treatment of cancer; the treatment of virus diseases, such as measles and anterior poliomyelitis with serum—all these, to mention but a few, have enormously extended the control of the physician and the surgeon over disease. "It can indeed be claimed," the report states, "without fear of serious contradiction, that the total amount of disability and the extent of human suffering have been immeasurably reduced by the combined efforts of investigators in all parts of the world during the period of existence of the Council." While the interest of the practising doctor lies mainly in the new therapeutic weapons these investigators have placed in his hands, he should remember that what is perhaps more important is the great strides medical research has made in the study of the basic problems of health and disease of the human body. Medicine is consolidating her claim to be a science as well as an art.

FOOD AND THE CHILD

Much has been heard about nutrition during the past few months, and since the report of the B.M.A. Committee on this subject the public has shown a wide interest in the two questions of how much and what sort of food the growing child requires. To these questions Dr. Robert Hutchison has given eminently sane and practical answers in his Hastings Popular Lecture, the text of which will be found in this week's *Journal* (p. 439).

Confining his attention to the problem of diet for the pre-school and the school child in this country, he emphasized at the outset how difficult it was to find an exact answer to the question of how much food the growing child needs. That the standards of nutrition commonly used in this country are unreliable, often being based on statistics collected in other lands, and none of them up to date, is an unfortunate fact, and the report now due of the special committee appointed some time ago to deal with the matter is awaited with interest. Even modern and exact data on height and weight for age standards, however, will not solve the problem, for, as Dr. Hutchison points out, malnutrition, when all is said and done, is essentially a clinical conception. The personal factor weighs so heavily that one group of experts can assert that economic conditions have barely affected the children of these islands, while another group, with equal conviction, assures us that the younger generation are certainly not so well nourished as they should be. The amount of energy required daily can be calculated along the lines Dr. Hutchison lays down of "the overhead charge" of basal metabolism, plus the requirement for activity plus the requirement for growth; and it is important to remember that children in their teens may consume and need more than full-grown adults. Nevertheless, even if the exact calorie intake of the child at any age, of any special bodily configuration, could be accurately calculated, this would still not ensure perfect nutrition. Too little time spent in sleep—a common and increasing fault among the present-day child population—means that more food is necessary, while, although physiologists assert for the cold comfort of the intelligentsia that brain work needs no fuel, there will be widespread agreement with the analysis put forward by Dr. Hutchison of the way in which modern educational methods in many instances interfere grossly with the physical well-being of the child. Granted a normal and healthy boy or girl the quantity of food necessary will be measured accurately by the appetite. The second question—as to what kind of food is required—can be more scientifically approached. The emphasis laid by Dr. Hutchison upon animal protein, and more especially upon the value of milk for its growth-promoting properties, echoes the statements made in the B.M.A. Committee's report, and it is satisfactory to note in passing that the "Children's Minimum Organizing Committee" now acknowledges the ambiguity of the term

"fresh" in the designation of the milk ration for all children attending State-aided schools and for younger children. As to the purity of the milk supplied we should here like to quote from a letter which appeared in the *Times* of March 5th under the signature of Lords Dawson, Moynihan, and Horder, Dr. J. A. Arkwright, and Sir Frederick Hobday: "The supply of milk to growing children will receive strong support from the medical profession, but until purity at the source and during subsequent distribution can be guaranteed it is imperative in the public interest that all milk should by adequate pasteurization be rendered safe from the risk of causing disease."

With the other elements of diet Dr. Hutchison deals in a broad-minded manner. This epithet is chosen deliberately, because there seems to be a tendency nowadays for so-called experts in dietetic matters to condemn or extol certain articles of food in a bewildering fashion. The one will anathematize sugar, a second condemn all cereals, a third attack the fat, and a fourth praise some special form of bread, until the public gives up what little faith it may have had in such pundits. The simple conclusion of one unit of protein, one of fat, and five of carbohydrate for the basis of the diet of the growing child is a thoroughly practical one. Dr. Hutchison wisely says that the importance of making special provision for the supply of vitamins is being over-estimated at the present time. There is no risk that this supply will fail if a pint of milk daily, animal fat, and green vegetables are included in the diet. If a deficiency is suspected the natural form of vitamins is advised in preference to the many artificial preparations now flooding the market. Dr. Hutchison's conclusion is the meal-time greeting in many lands and among many peoples, "Good appetite." Given this, the child can very well look after itself, provided there is food available.

CARBOHYDRATE METABOLISM IN GRAVES'S DISEASE

The association of disturbances in carbohydrate metabolism with Graves's disease is well known, but the mechanism of this association is not as yet understood, nor is there any agreement on the question as to whether the exophthalmic subject is more liable to diabetes than is the "normal." Before such matters can be decided the criteria by which abnormal carbohydrate metabolism is to be recognized must be more clearly defined. The time is now past when manifestations of abnormal carbohydrate metabolism could be referred simply to insufficiency of the pancreatic islets, and when faced with a glycosuria we have to consider the whole endocrine system before venturing a diagnosis. It is probable that this is true even in cases of the so-called "renal glycosuria" and "lag" types, and that there is too great a tendency to be content to place a case in one or other of these classes and leave the matter at that. From our knowledge of the metabolic effects of the thyroid hormone it is clear that manifestations of carbohydrate imbalance in such conditions as Graves's disease and myxoedema must be

expected. Recent work by W. T. Andersen¹ demonstrates that spontaneous glycosuria occurs in practically all cases of Graves's disease, and that this is due, not to a raised fasting blood sugar, but to an abnormally high and prolonged blood sugar curve after alimentation and a tendency to a somewhat lowered threshold. In explanation of this the author is inclined to accept Falta's hypothesis of a physiological antagonism between the thyroid and the pancreas, in that the former tends to diminish the formation of hepatic glycogen, whilst the latter promotes it. Persistent strain of the insulin mechanism in such cases might produce functional fatigue of the islets, and pancreatic diabetes might ensue. Andersen found that thyroidectomy was followed by an improvement in carbohydrate metabolism in pure Graves's disease, and by an improvement when this was complicated by diabetes (diminished insulin requirement, etc.). The recent demonstration by Houssay of the importance of the pituitary in the aetiology of diabetes, and the known relation between the thyroid and the pituitary, makes it more than probable that the thyroid is involved in so-called pancreatic diabetes. To support such a view it is not necessary to seek the extreme forms of Graves's disease among a series of diabetics. Indeed, the incidence of Graves's disease in a large series of diabetics was found long ago by van Noorden to be only about 0.6 per cent. Evidence is accumulating that hyperthyroidism is often demonstrably associated with excessive anterior pituitary function (excessive amounts of anterior pituitary and female sex hormones in the blood and urine of non-pregnant exophthalmic patients), and it seems not unreasonable to assume that in such cases there is an excessive production of the pituitary diabetogenic factor. The problem is, however, complicated by such considerations as that myxoedematous subjects frequently show marked intolerance to carbohydrate; but this might be explained rather by the general depression of all the metabolic functions than by a selective hyperfunction of one of them.

HYPOGLYCAEMIA IN IDIOPATHIC EPILEPSY

In a previous reference to research in mental hospitals² we mentioned a series of studies then in progress in the pathological laboratory of the Gloucestershire county mental hospitals. The objective of this work seemed to be of particular interest in that it was related to the possibility of a metabolic disturbance being concerned in the production of idiopathic epilepsy—a condition of obscure aetiology in which some elucidation of this kind might well have a bearing upon practical therapeutics. The work has now been completed, and the investigator, Lieutenant R. L. Haviland Minchin, I.M.S., has reported conclusions³ which deserve serious thought. In view of the known facts that an anaemia of the brain results in a deprivation of glucose as well as of oxygen, and that lack of a sufficient glucose supply to the brain can of itself originate epileptiform symptoms, it was decided to investigate the blood sugar values of a series of epileptics, irrespective of the number, the severity, or the duration of their fits. It was thereby shown that epilepsy was associated with

¹ *Acta Med. Scand.*, 1934, Supp. liv.

² *British Medical Journal*, 1932, ii, 722.

³ *Journ. Ment. Sci.*, October, 1933.

a low fasting blood sugar content, and that the glucose tolerance curve in this disease revealed over-activity of the islets of Langerhans. Apart from the bromides, which damp the irritability of the cerebral cortex, those drugs which have been found useful in epilepsy raise the blood sugar level. The obvious preventive of epilepsy would thus appear at first-sight to be a high carbohydrate diet, but, unfortunately, the problem is complicated by the fact that such an excess stimulates the formation of insulin. It has also been borne in mind that marked hypoglycaemia has been successfully treated by a low carbohydrate diet, and child epileptics often do well on a ketogenic diet. The explanation may be that, just as a high carbohydrate diet stimulates the islets, so a low carbohydrate diet tends to diminish their activity. The cause of the hypoglycaemia in epilepsy remained to be worked out. No evidence suggesting hypothyroidism was obtained, and none of the cases in the present series showed any of the classical symptoms of hypopituitarism. The blood pressures and pulse rates of the patients excluded any notable abnormality of the suprarenal function, and no signs of liver deficiency were observed. The author comes, therefore, to the conclusion that hyperinsulinism is probably the cause of the low blood sugar figures found in epileptic patients. He points out that hyperinsulinism, with symptoms indistinguishable from those of clinical epilepsy, has been recorded lately in a number of cases; that the glucose tolerance test figures point to islet activity; that female epileptics have more fits at the menstrual periods, at which time it has been shown that there is an increased sensitivity to insulin (the high folliculin content of the blood activating the insulin present); and that the value of such drugs as the barbitones, chloral, and caffeine can be explained on these lines. In the Gloucestershire investigations it was shown also that in the period of post-epileptic confusion the glucose tolerance was much reduced, and that far higher blood sugar levels were present. Variation in the balance of the autonomic nervous system had only a very limited influence on the blood sugar concentration and the incidence of fits. Natural recovery from epilepsy was found to be associated with the onset of hyperinsulinism. A final suggestion is that in cases of epilepsy which do not respond satisfactorily to medical treatment the pancreas should be partially removed.

POST-VACCINIAL ENCEPHALITIS IN 1933

The permanent committee of the International Office of Public Health has recently drawn up statistics of the incidence of post-vaccinial encephalitis in different countries during 1933.¹ In England four cases were notified between April, 1932, and May, 1933, with one death, which occurred in a girl aged 17, in whom the symptoms developed on the eleventh day after vaccination. The other cases were in two young adults and a boy aged 7, who all made a rapid recovery. The lymph used in these cases came from different sources. Since April, 1933, the Ministry of Health has received reports of four cases without any deaths. In the first case, which occurred in a boy aged 13, the condition appeared to be one of poliomyelitis developing eleven

days after vaccination. The other patients, aged 15, 17, and 19, recovered rapidly without any sequelae. In three of these cases the lymph came from the State institute, and in one case from an authorized private establishment. In Holland five cases were notified, two of which were fatal, but as neither was examined by a neurologist the diagnosis was not absolutely certain. The other three cases were mild attacks in children aged 3 years. The annual number of vaccinations in Holland, which was formerly as high as 150,000, has of recent years considerably diminished, being 30,000 in 1932 and only 25,000 in 1933, so that the proportion of encephalitis is about one for every 5,000 vaccinations, as it was in previous years. In Sweden, where thirty-six cases with eight deaths occurred between 1924 and 1933, the number of cases is about one to every 20,000 vaccinations. In Germany fourteen cases occurred among the primary vaccinations with one death, and five cases with two deaths among the revaccinations during 1933. Every case notified was examined by a committee of specialists. During the period 1927-33 there were 134 cases with thirty-nine deaths among a total of about fourteen million vaccinations or revaccinations.

PARALYSIS AFTER ANTI-SCARLET-FEVER SERUM

From time to time cases have been recorded in which paralysis has occurred after the use of antisera. I. M. Allen² reported the case of a man, aged 22, who developed brachial neuritis and amyotrophy after a prophylactic injection of 10 c.cm. of antiscarlatinal serum. He classifies the neurological complications of serum sickness into four types: (1) radicular, resembling Erb-Duchenne paralysis of acute onset; (2) neuritic, in which single nerve trunks are affected; (3) polyneuritic, with symptoms of toxic polyneuritis; (4) cerebral, in which the signs and symptoms are probably due to cerebral oedema. The prognosis is considered to be good. Three cases of musculospiral paralysis and one of facial paralysis after the prophylactic injection of scarlatinal antitoxin have been reported by A. Gordon,³ who states that the prognosis is invariably favourable, and considers that, in view of the rarity and transient nature of the paralyses, this complication of serum therapy is no contraindication to its use. A further account of paralysis after anti-scarlatinal therapy is given by J. Cathala, R. Garcin, P. Gabriel, and R. Laplane.³ Their patient, an unmarried woman aged 25, had, in 1928, received injections of antidiphtheritic serum without any misadventure. On April 3rd, 1932, she was admitted to hospital with scarlet fever and was given an injection of 60 c.cm. of antiscarlatinal serum on the same day. A fortnight later a typical serum reaction occurred, with generalized urticaria and Quincke's oedema of the face. During the following night severe pain developed in the shoulders, nape of the neck, and right leg. The right arm, the left arm, and right leg became paralysed, the one after the other, in the course of a quarter of an hour. Partial recovery followed four days later, but on May 27th, fifty-four days after the injection of the serum, a second attack of urticaria developed while

¹ *Lancet*, 1931, ii, 1128.

³ *Presse Médicale*, January 13th, 1934.

¹ *Bull. Off. Internat. d'Hyg. Publ.*, 1934, xxvi, 75.

the patient was menstruating; it lasted a few days. On May 30th severe pain was suddenly felt in the left arm, which within an hour became paralysed. On June 18th a third outbreak of urticaria, lasting only a few hours, was again the signal for a recurrence of the cervico-brachial pain. As late as September, 1933, both arms were still very weak, though their range of movement was beginning to return to normal. Discussing possible explanations of this case, the authors refer to Sicard's hypothesis; according to this there is an internal urticarial condition which exerts pressure on branches of nerves, which become strangled in their sheaths.

TEMPERAMENT AND TOFFEE-MAKING

A report of the Industrial Health Research Board, by S. Wyatt (assisted by L. Frost and F. G. L. Stock), on "Incentives in Repetitive Work" gives a detailed account of a practical experiment in a toffee-making factory. The object of the experiment was to discover the chief factors controlling the output of a group of girls engaged on the monotonous tasks of wrapping, packing, and weighing pieces of toffee. The investigators kept a group of ten girls under close observation for a period of fifteen months, and, as girls of widely differing temperament and intelligence had purposely been chosen, study of their reactions to the work yielded results of great practical importance, as well as being of psychological interest. The girls worked in pairs for a day at a time on each of five tasks, and they all worked through the same programme. As their occupations contained little that was inherently interesting the most important incentive to good work proved to be the weekly wage. When the girls were on a time rate they all worked comparatively slowly, and only constant supervision and the fear of dismissal kept them up to the mark. They found the routine extremely boring, and wasted a good deal of time in voluntary rests; but the system tended to promote friendly relations, and instances of envy and jealousy because one worker did more than another were comparatively rare. When the girls were put on to a piece rate their output improved about 40 per cent., and they found their tasks distinctly less boring. Unfortunately they became more quarrelsome, envious, and jealous of one another. The more capable found their work satisfying, but the slower ones got discouraged and depressed at seeing their neighbours earning a substantially higher wage than themselves. The remedy seems to lie in the selection of workers, so that each group consists of individuals who are approximately equal in capacity. This capacity did not appear to depend on the manual dexterity of the girls—which was estimated by getting them to work for short periods at high speed—but on their possession of a quiet and placid temperament, and immunity from distracting influences and from a disposition to quarrel and complain. The talkative, dominating, and quarrelsome members of the group, though possessing considerable manual dexterity, had the worst output, because their rate of work was so erratic. They had a disturbing effect on the others, and the temporary absence of one of them caused an increase of 13 per

cent. in the output of the remainder. It was found that the temperamental tendencies shown by the girls were well known to their school teachers, so it seems probable that school records kept by observant teachers are likely to provide the most trustworthy evidence of general suitability for repetition work in industry.

CREMATION IN GREAT BRITAIN

A comparative table of cremations, issued the other day by the Cremation Society, reveals that this method of disposal of the dead is steadily winning favour in this country, and not least in industrial areas. Comparing the figures for the years 1929 and 1933, it appears that the percentage increase has been: 200 for Pontypridd, 140 for Liverpool, 128 for Darlington, 98 for Bristol, 95 for Birmingham, and 87 for Bradford. Moreover, the new crematoria start with much higher figures than was the case formerly. For example, the first year's totals for Reading and Southampton are equivalent to those at Birmingham and Manchester after sixteen and twenty-six years respectively. In 1933 there were 7,480 cremations at the existing twenty-four crematoria, in comparison with 6,315 in 1932, and 5,195 in 1931. The pioneer crematorium, at Woking, was opened in 1885, and has now cremated 8,934 bodies, and the Golders Green establishment, on the outskirts of London, which opened in 1902, has cremated 28,884. Those at Reading and Southampton started operating in 1932, and drew away a number of cases which would otherwise for the most part have been dealt with at Woking. There are four kinds of controlling authorities—namely, burial boards with three crematoria, municipal with ten, proprietary with ten, and in one instance the State, operating in Guernsey. In addition to new crematoria nearing completion at Newcastle-on-Tyne and Stockport, others are already authorized or are contemplated by the local authorities at Birkenhead, Blackpool, Croydon, Maidstone, Plymouth, and Stoke-on-Trent. The regional increases suggest that some of the wage-earning classes are now tending to adopt cremation, notwithstanding their traditional preference for the slow corruption of the grave. How anyone with the least spark of imagination can hesitate between earth burial and the quick furnace passes our comprehension. But racial habits die hard, and we know of many confirmed believers in cremation for its hygienic and aesthetic advantages who have failed to leave directions for the disposal of their own bodies by this means, or have let members of their families be buried when the day came for putting a principle into practice. "Another time, another time," they say.

THE ROYAL SOCIETY

Among the seventeen candidates recommended by the council of the Royal Society for election as F.R.S. are: Paul Fildes, M.B., B.Ch., research bacteriologist at the London Hospital; R. T. Grant, M.D., M.R.C.P., lecturer in cardiac pathology to University College Hospital Medical School; E. L. Kennaway, M.D., director of the research laboratory at the Cancer Hospital; and H. Raistrick, D.Sc., professor of biochemistry in London University.

The Hastings Popular Lecture

ON

THE FOOD OF THE GROWING CHILD

Delivered in the Great Hall of the British Medical Association on March 7th

BY

ROBERT HUTCHISON, M.D., F.R.C.P.

The lecture which I have the honour to deliver this evening is in memory of Sir Charles Hastings, the founder of the British Medical Association; and it is right that his name should be kept in remembrance, for in founding the general interest. Now there is no subject bearing on the medical profession, but, indirectly, on the public whom that profession exists to serve. By the condition of its foundation the lecture is intended to be a popular one, and to deal with some aspect of the public health of general interest. Now there is no subject bearing on the public health which is at present more in the minds of the laity than that of nutrition, for there is a widespread apprehension that, owing to the present economic stress, certain sections of the community may suffer from imperfect nutrition, with all the consequences to health which such a condition involves. Further, if malnutrition exists, it is always on the youngest members of the community that its evil effects chiefly fall, and I propose, therefore, to consider the amount and kind of food necessary for the proper nutrition of children of the pre-school and school age—say, from 3 years upwards. I shall not touch upon nutrition during infancy, as that presents special problems of its own. Further, what I have to say applies only to children in this country, for it is of these alone that I have any personal experience.

WHAT IS OPTIMUM NUTRITION?

At the outset we are met by the question, What is proper nutrition, and how do we know whether a child is well nourished or not? Various criteria have been proposed, of which "weight for height" and "weight for age" are most generally employed; but unfortunately these do not apply to the individual child, but only to the average child of a group. When all is said and done, "malnutrition" is mainly a clinical conception, and although an experienced doctor can say with fair certainty that such-and-such a child is suffering from it, yet it must be remembered that there is a large personal factor in his judgement; and this must always be borne in mind when you read that so many children in, say, a school are reported to be "ill nourished."

There is another question equally difficult: At what standard of nutrition are we to aim in our feeding of the growing child? At a maximum deposition of fat? Surely not. Or at a maximum of muscle or height? It is very doubtful. Is the most muscular child necessarily the healthiest or the most likely to live long? Is height really an advantage? There is some evidence that town-bred children are smaller and lighter for their age than country children; but is that a bad thing? May it not be that Nature, if left alone, is evolving a type of individual best suited to stand the conditions of town life? I raise these questions at the outset, not to discuss, still less to try to settle them, but in order to bring home to you the fact that the problem of adequate nutrition in childhood is not so simple as might be supposed, and that we have still much to learn about it.

AMOUNT OF ENERGY REQUIRED

Notwithstanding these uncertainties science has taught us a good deal, especially in recent years, as to the essentials of healthy nutrition in childhood. We may

consider (1) the amount and (2) the kind of food required by the growing child, for the subject has both a quantitative and—equally important—a qualitative aspect. By the amount of food required one means, scientifically, the amount of energy which has to be consumed in the form of food in order to make good the outgoings of the body. These outgoings are in three directions: (1) the energy required to "run the machine" (what is called by physiologists the basal metabolism); (2) the energy used up in bodily activity; and, at the time of life of which we are speaking, (3) the energy required for growth. We must consider each of these separately.

The Overhead Charge

Even when the child is asleep in bed energy is being used up in the work of breathing, of circulating the blood, of keeping the body warm, and in other ways. This is an unescapable "overhead charge" which must always be provided for first if life is to go on at all, and about one-half of the total amount of food taken may be consumed in this way. The amount of energy required to run the machine is fairly constant for children of the same weight; but not absolutely so, for there is some reason to believe that certain individuals are more economical machines than others, whilst children who are under weight seem to have a higher "overhead charge" to meet than normal. On the other hand, prolonged malnutrition appears to bring about a more economical running of the machine, though this may perhaps be at the expense of health. The overhead charge is raised if more heat has to be produced, and this must be borne in mind in connexion with the question of open-air schools, for if children are to serve as radiators for warming the circumambient air they must be provided with enough food to enable them to do it. Parents and others who believe in "hardening" children by making them wear a minimum of clothing should also remember it.

Activity Requirement

That energy is required for growth is not so easily understood, and it is hardly necessary to point out that the amount of this item on the debit side of the balance sheet will vary greatly with the temperament of the child—active, restless children spending much more than the lethargic and placid. It is this factor, indeed, which chiefly accounts for the very different quantities of food required by different children of the same weight and age. I shall have something to say about some of its other implications in a moment. On the other hand, there is no reason to suppose that brain work involves any large expenditure of energy, and therefore of food intake. It is play and games that count, not lessons. Excessive brain work may, indeed, interfere with the nutrition of the growing child, but it does so indirectly in a way to be spoken of later.

Growth Requirement

That energy is required for growth is not so easily understood. It is simple enough to see that building material is required for that purpose, but it would appear that energy is also employed in, so to speak, "putting the bricks in place," and during the periods of most active growth this may come to quite a considerable amount—say about one-seventh of the total food consumption. Hence it is that a growing boy of 13 to 18 may consume (and need) more food than a full-grown man, and a girl of 11 to 16 more than an active woman.

ACTIVITY VERSUS GROWTH

When the overhead charge has been met there is a struggle between the demands of muscular activity and those of growth for what is left of the energy contained

in the food. If the diet is ample both activity and growth will go on to their full extent; if, however, food is insufficient, then one or other has to go short. If the demands of growth, under the urge of endocrine secretions, are imperious, there may not be enough food energy left over to admit of full muscular activity, and in the common phrase the child is said to have "outgrown his strength." If, on the other hand, muscular activity is forced and excessive, growth may suffer. This should be remembered by the advocates of compulsory games, and has to be considered in connexion with the question of adolescent labour. The competition between the demands of activity and those of growth also explain the well-known fact that children often grow rapidly when they are confined to bed through illness, and it emphasizes the importance of ample hours of sleep to the growing child, for during sleep all demands on the food energy, except those of growth, are reduced to a minimum.

CAUSES OF MALNUTRITION

It will be obvious from what has been said that malnutrition in the child may result not only from an insufficient income of energy in the form of food, but also from excessive expenditure, the result of overactivity and too little sleep. But it may also come about in another way. The food supply may be abundant, and yet, owing to impaired appetite or enfeebled digestion, the child may not be able to avail himself of it. I believe these disorders to be fairly common causes of malnutrition among children of all classes to-day. They are brought about by two circumstances—on the one hand by town life, with all that it implies in the way of overcrowding and want of fresh air and exercise, and, on the other, by educational overstrain. Both of these factors are at work, and often together, to lessen the child's desire for food and power of making use of it, apart altogether from the question of whether enough food is available or not. The amount of physical pabulum a child can take in is, as it were, in inverse ratio to the amount of mental pabulum you try to put into him, so that the activities of the Ministry of Health and those of the Board of Education often run counter to one another.

AMOUNT OF FOOD NEEDED

Having summed up the debit side of the balance sheet of energy, you may now ask, What does it all amount to, and how much food must the growing child take in order to meet it? Unfortunately, as far as the *individual child* is concerned, no one can tell you. Physiologists, it is true, have calculated with a fair degree of accuracy the amount of energy in the form of calories (the unit employed in measuring the energy value of foods) required by the average child at different ages; but as regards the individual child we have only its appetite to guide us, which, after all, is Nature's index of food requirements, and a fairly trustworthy one. We can only trust it, however, if the appetite is normal and healthy, and that, as I have already said, is by no means always the case. If, then, we wish to promote optimum nutrition in the growing child, we must see to it that the appetite is normal, and that may mean changing the child's whole mode of life. Once the appetite is normal the amount of food required may safely be left to the child itself to determine.

PROTEIN REQUIREMENT

We now turn to the qualitative side of our problem. What *kind* of food does the growing child require? The energy of which we have been speaking may be derived from any of the nutritive constituents of the food—protein, carbohydrates, or fats—but it is by no means a matter of indifference what proportion of the total

energy is derived from each. As regards proteins we have no choice, for they alone of the nutritive constituents are able, not only to supply energy, but to provide the raw material necessary for growth and repair. The kind of protein supplied is, however, of importance, for some proteins go farther than others as growth material. Broadly speaking, the animal proteins are more valuable in this respect than those of vegetable origin, and a considerable part—say one-half—of the total protein supplied to the growing child should be derived from animal sources. This means in practice that milk, eggs, cheese, meat, and fish must be adequately represented in the diet, milk particularly seeming to have a special power of promoting growth.

FATS IN NUTRITION

The remainder of the total energy required must be taken in the form of fats or carbohydrates, and it might be thought that it did not matter which was chosen, always bearing in mind that a given weight of fat supplies more than twice as much energy and heat as a given weight of carbohydrate. There is some reason, however, to suppose that fats play a part in nutrition which carbohydrates cannot fill. For one thing, most animal fats are the vehicle of important vitamins—of which more later—but, apart from this, fats seem to have the power of increasing the resistance of the body to certain diseases—especially tuberculosis. Lastly, it has been claimed for them that they are a "nerve food," and that children who take fat well are not so subject to functional nervous disorders as others. It must also be remembered that the digestive organs are less likely to be strained if a mixture of fats and carbohydrates is taken rather than either alone, or disproportionately. Unfortunately, the capacity of children to take and digest fats varies greatly; and there is some reason to believe that the modern child shows an increasing disability in this respect; but whether this be so or not, every effort should be made to educate the growing child—for it is to some extent a matter of education—to digest a reasonable amount of this important constituent of the diet.

STARCH AND SUGAR

With the carbohydrates there is no difficulty. All children like them, and the only danger is that, partly on this account and partly because of their relative cheapness, an undue proportion of the total energy of the diet may be supplied in carbohydrate form. This danger especially applies to sugar, which is now so cheap, which is presented in such seductive shapes, and which children take so readily. To some extent, of course, the craving of the young for sugar is a natural one, but if indulged too much both appetite and digestion suffer. Furthermore, an excess of sugar in the diet may even predispose to disease. There are some doctors who believe that it favours catarrhs, though this cannot yet be regarded as proven, and there are strong grounds for supposing that it may sometimes lead to the development of diabetes. In these days, when the indiscriminate administration of glucose to children is so common, it may be worth while to bear these possibilities in mind.

To sum up, and in order to give some practical exactitude to the above considerations, it may be said that the food of the growing child should contain for every unit of protein one unit of fat and five of carbohydrate, and that in the latter starch should largely preponderate. The exact figures, of course, will vary with the age, temperament, and digestive peculiarities of the individual child.

But in considering the qualitative aspects of the child's diet we have to reckon not only with the kind of nutritive constituents from which the energy is obtained (proteins, fats, and carbohydrates), and in what proportion from

each, but also with substances which, although not supplying energy, are yet absolutely essential for healthy nutrition—namely, the mineral matters and the "accessory food substances," popularly known as vitamins. The discovery of the importance of these, and especially of the vitamins, has been the chief contribution of the present century to the science of nutrition.

MINERAL MATTERS

The mineral matters we may dismiss briefly, for whilst it is true that several mineral substances are required for proper nutrition, there are only two—calcium and iron—which are ever in the least likely to be deficient in the diet. Calcium is especially important for the growing child, seeing that it enters so largely into the composition of the bones. It is contained in abundance in milk, cheese, eggs, and green vegetables, and so long as these are well represented in the diet no shortage of it need be feared. It is, indeed, impossible to name any disease of childhood which is due to too little calcium being supplied in the food, although conditions of ill-health may result from failure to utilize it when it is supplied. Deficiency of iron also does not arise unless the diet is very faulty in other respects as well. Iron is most abundant in red meat and in yolk of egg, and in oatmeal, spinach, and some other vegetable foods, but if there is any reason to suppose that the growing child is not getting enough iron it is easier to supply the metal in the shape of medicine rather than in that of food.

VITAMINS

The vitamins cannot be dealt with so shortly, but as Professor Mellanby discussed them fully in his Sir Charles Hastings Lecture three years ago, and with all the authority of one to whose experimental work much of our knowledge of them is due, I need only refer to them in so far as they affect the growing child.

There are, as most of you know, four vitamins which are of importance in nutrition—A, B, C, and D. The first and the last of these are "fat-soluble"; B and C are "water-soluble." Vitamin A is contained largely in milk-fat, yolk of egg, liver, and green vegetables, but is particularly abundant in fish oil. If a child is starved of it a curious disease of the eyes may develop (keratomalacia), and night-blindness may also occur. These conditions are both extremely rare, but outbreaks of them have been observed recently among children in some of the distressed areas in this country. It has also been claimed for this vitamin that it has the power of increasing resistance to infection, and it has therefore been called the "anti-infective" vitamin. There is no evidence, however, that it possesses this power in human beings, except as regards some minor infections of the skin, so that the term "anti-infective" is not justified.

The water-soluble vitamin B complex is the accessory factor which prevents the development of beri-beri, a disease, however, which never arises in this country. There is some experimental evidence that, apart from this disease, certain disorders of health may arise if the vitamin is supplied in insufficient amount, but such disorders, if indeed they arise at all, cannot be recognized in man. In any case vitamin B is so widely present in all sorts of foods that any deficiency of it in a reasonably varied diet is almost out of the question.

The other water-soluble vitamin, C, prevents scurvy, and is present in fresh fruits and vegetables and, in lesser amounts, in several other foods, such as potatoes. As scurvy almost never affects children beyond the age of infancy in this country there seems no reason to fear that vitamin C is often deficient in the diet, nor can we, in this case also, recognize any disturbances in health

short of actual scurvy which are due to a comparative though not absolute shortage of it. There is therefore no reason to give growing children large quantities of orange juice, as is so often done now, in order to supply "vitamins."

The other fat-soluble vitamin, D, is the one which prevents rickets. It is present in yolk of egg, butter, and milk, and in fish oils, and is highly important in the diet of infancy; but there is no recognizable disease of childhood due to a deficiency of it unless—as the recent work of Mrs. Mellanby suggests—caries of the teeth is an indirect consequence of such a defect.

As regards the question of the vitamins in general, I am of opinion that their importance is being over-estimated by the public at the present time; or perhaps it would be better to say that the importance of making *special provision* for them is over-estimated. If the diet is right in other respects, and especially if it contains a reasonable amount of milk (say a pint a day), animal fat, and green vegetables, then the vitamins may be left to look after themselves. Should you, however, fear that a child's diet may be deficient in the most important of the vitamins—the fat-soluble—I should advise you to supply them in a natural form, such as fish oil, rather than as one of the many artificial preparations with which the market is now flooded.

CONCLUSION

In conclusion, I would say for your comfort that the choice of food for the growing child is not really a very abstruse or difficult matter after all. If the diet is abundant, mixed, and varied, and in accordance with the essentials sketched out above, all will be well, provided always that the child has a good appetite. But that "provided" is the crux of the whole matter, for I hope I have said enough to convince you that *proper nutrition* is not a matter of food alone, but of the child's whole nurture.

INDUSTRIAL HEALTH EDUCATION SOCIETY

The annual meeting of the Industrial Health Education Society was held on February 28th at the house of Lord Luke in Portman Square. Lord LUKE, who is chairman of the executive council, said that the society, in the ninth year of its history, had been very active. Its work consisted in arranging health talks and exhibitions of health films to workers' organizations throughout the country, and during 1933 the total of lectures given had amounted to 395. The society was much indebted to miners' lodges, trade unions, and other bodies, which arranged for the rooms, and brought together the audiences, while the society itself supplied the speakers. In the report which was presented it was mentioned that the society hoped to do more for women workers; the reason why addresses to women had been less frequent than to men was because women workers were not so well organized. The society had been able to carry out so much work on an expenditure of £1,500 simply because of the arrangements made locally and the willingness of the doctor-lecturers to give their services for a modified fee of one guinea.

Lord HORDER said how proud he was to be president of the society. He thought it was all to the good that industrial health education should do its best to keep pace with the lessening of unemployment. He noted that the subjects dealt with in the talks given nine years ago, when the society was first formed, were rather different from the topics now more generally selected, and this was quite right, because it showed that the efforts of the society were keeping pace with the needs of the worker. Of late years the incidence of serious occupational diseases had diminished to a very large extent. He had in mind such diseases as lead poisoning,

anthrax, and silicosis. On the other hand, the question of nutrition had come more and more into the picture, also minor illnesses, constipation, the common cold, troubles of the skin and of the teeth, and the care of the hands and feet. Even vague ill-health, described as "nerves" or "fatigue," had been the subject of various talks. It was evident that the tendency was away from the acute and violent and mortal organic diseases, but in place of these the people were becoming a prey to subtle chronic functional disabilities, and he was glad to see that these conditions were being dealt with in the right way by medical men, of the desired status and qualification, in their talks to the workers in different parts of the country. The society linked up with the Institute of Industrial Psychology, and, of course, with the Ministry of Health in its activities in regard to preventive medicine. For his own part he would like to see it linked up with another series of activities—namely, those having to do with engineries, but that, perhaps, would be considered a little premature at the present moment.

Sir THOMAS OLIVER, in a very few remarks, sketched the history of industrial medicine during the last hundred years, and mentioned how much had been done within his own experience to lessen the mortality from occupational diseases. By attention to industrial hygiene and the substitution in many cases of harmless for harmful agents some occupational diseases had been entirely eliminated, and the liability to others had been greatly lessened. It was to the credit of employers and employed that in the main the visits of those concerned in factory inspection had been received in a friendly and co-operative manner. Again and again workers had said to him that if they had only known of the dangers to which they had been exposed they would have taken greater precautions. It was to supplement the information given by official sources and to bring it home to the worker and also to his family that the Industrial Health Education Society existed, and he wished it every success.

The necessary business of the annual meeting was transacted, and a few remarks were made by Sir W. S. Haldane, Dr. E. G. Annis, Dr. G. Clark Trotter, and Dr. D. A. Coles in proposing the adoption of the reports and the re-election of the officers and council.

THE "MEDICAL SICKNESS" JUBILEE DINNER

The Medical, Sickness Annuity and Life Assurance Society, Limited, founded in 1884, held a dinner on March 1st, at the Dorchester Hotel, Park Lane, to celebrate its jubilee. The chairman of the board of directors, Dr. F. C. MARTLEY, presided over a large company.

The toast of the evening was proposed by Sir HUMPHRY ROLLESTON, Bart., who described Mr. Ernest Hart, the originator of the society, as a "live wire." He was Editor of the *British Medical Journal*, and in that and in other capacities he certainly made enemies, but he had qualities which enabled him to do much for the British Medical Association, as well as to plan out the mutual provident association whose fiftieth anniversary was now being celebrated. Hart was the society's first chairman; Sir Spencer Wel's also shared a good deal of the responsibility. The personnel of the society had changed very much with time, but the present directors were a very robust body, and the society was especially fortunate in having at its head Dr. Martley, who had been a principal factor in the continuing success of this enterprise, and in addition to being a good doctor was a good man of business and statistician. He hoped that the society might long flourish, and Dr. Martley for many years preside over its affairs.

Dr. MARTLEY, who was received with enthusiasm, said that at the commencement of the society Ernest Hart got a number of men together and said, "Let us all consider ourselves insured, but agree not to claim anything for a year, until we get some money together." A couple of hundred people, with no great amount of money, but with benevolent intentions, were got together, and the society had never looked

back. Some of those founders still lived; one of them, Dr. Moses Biggs, who was in his eighty-fifth year, would have been present that evening but for the inclemency of the weather. Hart and his associates realized that the profession wanted an insurance society on business lines. For twenty-five years it was on the lines of a friendly society, and expanded slowly. Restricted in some respects by the Acts regulating friendly societies, the society was registered after the war as a limited company, and this had proved to be an unqualified success. The membership had more than doubled, and the assets had risen from £300,000 to over £1,000,000. The money was under the management of doctors; nobody else had any hold over it, and there were no shareholders to absorb the profits. During the past ten or twelve years the society had been advancing money for the purchase of practices and of houses, and notwithstanding the difficulties of the times, not one penny had been lost.

Sir WILLIAM WILLCOX, in proposing the health of the guests, said that he and the others on the board left it a privilege to be able to encourage thrift among members of the profession, and, particularly, among the newly qualified. Many of the older men had been through the mill, and knew how difficult it was to make a start; they sympathized with the young doctor who wanted to buy a practice, or get married, or take a larger house. He expressed the pleasure of the directors in seeing so many distinguished friends present on that occasion. In a special welcome to the representatives of the British Medical Association—namely, Dr. E. K. Le Fleming, Dr. G. C. Anderson, Dr. N. G. Horner, and Mr. L. Ferris-Scott—he pointed out that the society was really the child of the British Medical Association, and he hoped that that fact would not be forgotten in Tavistock Square.

Sir ARTHUR ROBINSON, Permanent Secretary of the Ministry of Health, who responded to the toast, said that he noticed that the income of the society had suddenly bounded up from small beginnings to about £30,000. The great increase had begun about the year 1912, a year of some importance, because it was then that the national health insurance scheme was launched. He wondered whether there was any relation between this bounding up of income and the institution of insurance practice!

Lord HORDER, who also responded, said that he doubted whether he should be regarded as a guest, for he was really a member of the society, having years ago joined a body which the society had absorbed. He congratulated the "Medical Sickness" on its phenomenal success, a success, moreover, achieved by doctors, although the fallacy was still current that doctors lacked the business instinct. He had had distinguished students through his hands in whom he had recognized business abilities of a high order, and the experience of the society confirmed him in rejecting the idea that doctors were not good men of business.

Among others present, in addition to those already mentioned, were: Sir Holburt Waring (President, Royal College of Surgeons), Professor W. Langdon Brown (Regius Professor, Cambridge), Mr. V. Warren Low (President, Royal Society of Medicine), Sir Francis Fremantle, M.P., Sir Walter Kinnear (Ministry of Health), Sir Milsom Rees, Dr. Robert Hutchison, Dr. David Forsyth, Dr. G. Roche Lynch (Home Office), Mr. H. A. T. Fairbank, Professor C. G. Lowry (Queen's University, Belfast), Mr. A. E. Webb-Johnson, Dr. J. Murray Bhgh, Dr. E. D. Macnamara, the deans of Leeds and Bristol Universities, the deans of King's College, London, St. Mary's Royal Free, University College, and Westminster Hospital Medical Schools, representatives of the Medical Defence Union, Royal Medical Benevolent Fund, Epsom College, and the principal insurance companies, and the directors and officers of the society.

J. de Sauvage Nolting (*Nederl. Tijdschr. v. Geneesk.*, February 3rd, 1934) maintains that there is a remarkable relation between dementia praecox and allied schizophrenic psychoses and the season of birth. Investigation of 2,589 such cases showed that the majority of patients who subsequently develop schizophrenia are born during the winter months. It is stated, however, that further investigations are needed in order to establish conclusive evidence.

Ireland

Milk and Tuberculosis

Professor Boyle, of the Agricultural School of University College, Cork, in a broadcast on "Milk and Public Health," stated there was no convincing evidence of any loss of nutriment in milk as the result of pasteurization. The most important disease conveyed through cows, he said, was tuberculosis, but the danger was comparatively slight, the proportion of cows giving tuberculous milk being one in four hundred. Professor J. W. Bigger, School of Pathology, Trinity College, Dublin, in a letter to the *Irish Times*, stated he was not in a position to know if Professor Boyle had been correctly reported, but in any case it was undesirable to encourage the present Government of the Saorstát to follow the example of its predecessors in shelving the Milk Bill, the introduction of which had been promised, at frequent intervals, for the past five years, and which was urgently required. The estimate of one in four hundred as the proportion of cows giving tuberculous milk was much lower than that usually accepted. It was apparently derived from the report of the Interdepartmental Committee on the Milk Supply (1928), and was arrived at from the finding that six (2.66 per cent.) of the milks of 225 herds, comprising 2,343 cows, contained tubercle bacilli, by assuming that there was, in each of the positive herds, only one animal giving tuberculous milk—an improbable assumption, made, obviously, to minimize the prevalence of the condition among cows in this country. In England the proportion was recently stated by a medical officer of the Ministry of Health as 1 to 2 per cent. Dr. Bigger stated he was not aware of any evidence suggesting that Irish cows were notably less affected with tuberculosis than those in England. The fact that 32 per cent. of the cows slaughtered in Dublin were tuberculous showed how prevalent was the disease. Professor Boyle, as quoted, neglected to point out that, whatever might be the proportion of cows yielding milk containing tubercle bacilli, the proportion of samples of milk as sold containing the organism would be much greater because the milk of a single tuberculous cow could contaminate a whole churn. This explained why 14 per cent. of churn samples in Manchester, 10 per cent. in Aberdeen, Dundee, Edinburgh, and Glasgow, and 9.3 per cent. in London had been found within the past four years to contain living tubercle bacilli. With the exception of the improvements effected in Dublin as a result of the exertions of the medical officer and of the chief veterinary officer, Dr. Bigger did not know of any great improvements which would tend to reduce the proportion of Irish milks containing tubercle bacilli below the figure, 8 per cent., which he found in 1920. In 1932 there were, in the Saorstát, 818 deaths from non-pulmonary tuberculosis. At a very conservative estimate 25 per cent. of these were due to the bovine type of tubercle bacillus, infection being caused by the consumption of tuberculous milk. He was quite unable to regard as "comparatively slight" any danger causing the death each year of 204 persons, many of whom were children. Professor Boyle recommended that "where there was any doubt the milk should be pasteurized." Pasteurization would enormously reduce the risk of contracting tuberculosis by the consumption of milk from tuberculous cows. It would not, however, entirely eliminate the danger, since the process required the bulking of large quantities of milk, ensuring in this way the almost constant presence of tubercle bacilli in the milk entering the apparatus. Moreover, in pasteurization the safety factor afforded by the temperature and time was such a narrow one that any error,

human or mechanical, might allow tubercle bacilli to survive the exposure of heat. In a recent report issued by the Department of Health for Scotland it was stated that 2.8 per cent. of 1,243 milks pasteurized by the "holding" method, which was undoubtedly the safest one, were found to contain living tubercle bacilli. Dr. Bigger regretted that the head of an agricultural department should advocate pasteurization instead of the elimination of tuberculosis from herds. Pasteurization was a very useful and, at present, necessary process, but it was not a substitute for healthy cows. In the investigation of the Scottish Board of Health out of 714 samples of Certified and Grade A (T.T.) milk examined only one was found to contain tubercle bacilli, a percentage of 0.14, as against the 2.8 per cent. of pasteurized milk.

Suggested Drastic Reduction in Fees for Anaesthetics

In a recent circular letter the following scale of fees for the administration of anaesthetics was "suggested" to the Minister for Local Government and Public Health. For comparison a scale of fees sanctioned in 1926 by the then Minister for Local Government and Public Health is also given.

Suggested Scale in 1934

	1 Case	2 Cases	3 Cases	4 Cases	Each Additional Case Over 4
	£ s. d.	£ s. d.	£ s. d.	£ s. d.	£ s. d.
Major operations ...	1 1 0	1 10 0	2 2 0	2 10 0	—
Minor operations ...	10 6	1 1 0	1 10 0	2 2 0	5 0
Tonsils and adenoids	5 0	10 0	15 0	1 0 0	5 0

This refers to one case per day, or two cases per day, as may arise. The fees may be increased by 100 per cent. where the operations are performed at night—that is, from 9 p.m. to 8 a.m.

Scale Sanctioned in 1926

- £1 1s. For administering anaesthetic.
- £2 2s. For administering anaesthetic and assisting at operation.
- £2 2s. For difficult maternity case in day (8 a.m. to 10 p.m.).
- £3 3s. For difficult maternity case at night (10 p.m. to 8 a.m.).

Enniscorthy Mental Hospital

Dr. D. L. Kelly, inspector of mental hospitals, in his recent report concerning the Enniscorthy Mental Hospital, stated that there were 508 patients in residence at this institution when he made his annual inspection. During the year seventy-three patients were admitted, fifty were discharged, and thirty died. The discharge rate was very satisfactory, and indicated that the treatment afforded was progressive. All deaths were due to natural causes, seven being attributed to tuberculosis. One necropsy was performed, but no inquest was held during the year. There were no cases of infectious disease among the patients or staff. Restraint was not practised with any patient, but seclusion in single rooms was necessary with fifteen patients, who were restless and excitable. The patients were afforded a great deal of liberty, and it was gratifying to record that, although they worked in the gardens without any attendants in charge, the escapes were very few. They attended the local cinema once a fortnight, while concerts, dances, and variety entertainments were also arranged. A piano and some table games had been purchased and a wireless set installed. A number of patients attended a circus on three occasions, and some coursing meetings.

Scotland

Ayr County Hospital

The report presented to the annual meeting of Ayr County Hospital on February 26th showed that the number of patients admitted to the institution during the year had been 1,764, including 1,533 surgical and 231 medical cases. The total ordinary income for the year had been £11,648 and the ordinary expenditure £12,773. A sum of £120 had been received in respect of treatment of cases under the Road Traffic Act. The deficit on the year's working after legacies had been included under income amounted to £333, and had been carried to the maintenance reserve account, which now stood at £3,861.

Control of Cancer

A meeting was held in the City Chambers, Edinburgh, on March 2nd to form a Cancer Control Organization for Edinburgh and the south-eastern area of Scotland. Lord Provost W. J. Thomson, who presided, said everyone was agreed that something might be done to facilitate the early diagnosis and treatment of cancer, as well as to encourage and co-ordinate clinic and laboratory research. The work of the proposed organization would be preventive and educative, and would not interfere with the activities of any existing organization. Mr. J. J. M. Shaw, in outlining the scheme, said that the south-eastern area of Scotland, with Edinburgh and its medical resources as a central point, formed an ideal region for a scheme of co-ordination. Approximately 1,000 cases of cancer in one form or another entered the Royal Infirmary for treatment every year. Any addition to our knowledge, or any improved methods of treatment of this disease, could only secure a reduction of the incidence and mortality gradually and steadily as facilities for diagnosis, treatment, and research were co-ordinated. The early stages of cancer were often painless, and this was responsible for the fact that so many patients failed to seek medical advice until the disease was in an advanced state. Team work and adjustment of ideas were essential in the work which they were now trying to encourage. The elimination of delay was the practical issue. It was proposed that there should be judicious dissemination of knowledge as to when the doctor's advice should be sought, through the medium of nurses, welfare workers, health visitors, and meetings of those who desired information. Much of the fear of cancer arose from ignorance. It was important to obtain full information concerning the results of all forms of treatment, and in this way to assist the National Radium Centre in so far as its services were common to all hospitals in the area. Mr. W. J. Stuart said it was obvious that one worker with a group of cases might take years to settle a single point, whereas the combined investigations of many workers might settle the question in a short time. It was desirable, therefore, to have some central body where the reports of all workers would converge, and from which any worker could obtain the most up-to-date statements. Dr. John Guy, medical officer of health, Edinburgh, stated that in 1898 there were some 265 deaths from cancer in Edinburgh, while last year there had been 785, facts which showed the necessity for action. Lady Findlay moved that a general council and executive committee should be elected to draft a constitution and to elect subcommittees. The following were elected as an Executive Committee: Sir Thomas Whitson (chairman of managers of the Royal Infirmary); hon. treasurer: Professor Annan; Dr. R. W. Craig (British Medical Association); Dr. Guy (medical officer of health, City of Edinburgh); Lieut.-Colonel Harvey (resident consulting

physician, Research Laboratory); Professor Murray Lyon (Royal College of Physicians); Dr. Scott, Broxburn; Mr. J. J. M. Shaw (Royal College of Surgeons); and Dr. Duncan White. It was intimated that subscriptions had already been promised amounting to approximately £500.

Edinburgh Mental Hospital

The 121st annual report of the Royal Edinburgh Hospital for Mental and Nervous Disorders, which was submitted at a meeting on February 26th by the physician-superintendent, Professor D. K. Henderson, shows that during the year 1933 1,035 patients were treated in Craighouse and West House, of whom 306 were voluntary and 729 certified. This figure included 822 patients on the register at January 1st, 1933, and 213 admissions in the course of the year. Ninety-eight patients were discharged recovered or relieved, twenty-five unimproved, and fifty-six died. The number of patients with slighter mental or nervous illness admitted to the nursing homes connected with the institution was 127, and 202 were admitted to the Jordanburn Nerve Hospital. There were 493 out-patients in attendance at the various out-patient departments. The report draws special attention to the out-patient departments, where advice is given. A clinic is held at the Royal Infirmary on Tuesday afternoons at 2 o'clock, and another at the Jordanburn Hospital every afternoon, also at 2 o'clock. The clinic at the Royal Infirmary is considered particularly valuable, because it establishes a relationship between psychiatry and general medicine, and helps to elucidate the personality of the patient and the emotional drives which, even in the presence of physical illness, are often important factors in the cause of the illness and the cure of the patient. The work of the clinic is facilitated by the services of a social worker, who investigates environmental conditions and economic circumstances contributing to the patient's breakdown. A psychological clinic is also held every afternoon under the direction of Professor Drever for the purpose of studying behaviour disorders in children, and giving advice on education and vocational guidance. These out-patient clinics are regarded as of special benefit, because they present an opportunity of seeing incipient cases and of familiarizing medical practitioners and the public with the fact that many forms of nervous and mental illness are remediable provided proper treatment is applied at the right time. While the standard of care in mental hospitals is higher now than it used to be, the report states, great benefit is also being derived from occupational therapy. Every patient, irrespective of his condition, can be employed and interested, provided he has a certain degree of co-operation. Attention is drawn in the report to the various agencies in the prevention of mental disorder, and to the necessity for reducing the large number of patients who constantly require admission to mental hospitals on account of so profound a degree of mental defect as to necessitate segregation for the greater part of their lives. In the past, heredity was accepted as something hard and fixed; now it was regarded as something which might be modified and helped. The misery that might be entailed by a defective stock was not sufficiently recognized. Laws governing the compulsory sterilization of those who were socially inefficient and who were likely to transmit similar defects to their progeny were drastic and of doubtful practicability. The recent report of the Departmental Committee on Sterilization stated that a case for compulsory legislation could not be established, but had suggested that a policy of voluntary sterilization might be justified. This would apply to mentally defective and disordered persons who were likely to procreate unhealthy, unstable, and defective children; the same principle might be extended to those suffering from certain specified grave

physical disabilities. It was well known, however, that a great proportion of the mentally defective occurred as variants in families which were otherwise quite healthy, while mental illness was more an acquired than a hereditary condition.

England and Wales

L.C.C. Hospital Staffs

At the last meeting of the London County Council before the election of the new Council, which took place on March 8th; several matters relating to hospital appointments came forward. No special fee has hitherto been approved for the service of anaesthetists employed in connexion with thoracic surgery; they have received the normal fee of 34s. a session. It is now proposed that in view of the highly specialized knowledge required of anaesthetists when employed in connexion with thoracic surgery, they should be paid, as and from March 1st, the same fee as is paid to anaesthetists at the plastic surgery unit at Hammersmith Hospital—namely, two guineas a session. When the enlargement of the deep x-ray and radium therapy unit at Lambeth is completed (which it is expected will be at the end of the present month) the radium unit at the North-Western Hospital will be absorbed into that at Lambeth Hospital. The staff in connexion with the unit at the North-Western Hospital consists of an honorary medical director and an assistant to the director, both part-time, with a woman clerk and ward sister, all of whom will be transferred to Lambeth. The positions of honorary medical director and assistant will be reviewed with the general consultants' scheme before June 30th next. The titles of the positions will be "consultant (uterine cancer) to the radium unit" and "assistant consultant." An ante-natal clinic at Dulwich Hospital will be ready at the end of March, and an additional house-physician is to be appointed there, in view of the considerable increase in the work of the hospital, especially in connexion with the maternity department.

The Cancer Campaign in Wiltshire

A large number of Wiltshire medical practitioners and representatives of public health authorities in that county attended a meeting convened at Bradford-on-Avon on February 21st, when an address on the work of the British Empire Cancer Campaign was delivered by Mr. Comyns Berkeley, F.R.C.S., a member of the Grand Council of the Campaign, and vice-chairman of the National Radium Commission. The lecturer opened with an account of the pathology of cancer, emphasizing the point that, while the disease always started as a local growth, invasion soon ensued, and the possibilities of successful treatment were very seriously diminished. Despite the work of large numbers of research workers in all parts of the world, the cause of cancer still remained unknown, but an immense amount of valuable information had been collected which indirectly, by the elimination of certain previously presumed causes, was narrowing the field of inquiry, and bringing nearer the time when definite knowledge about the causation of cancer would be obtained. It was agreed that chronic inflammation due to prolonged irritation of the body tissues was a constant factor in the production of some varieties of the disease. No evidence had been obtained that the disease was hereditary, and the personal risk was not increased because a parent or grandparent had had it. There was no known instance of one person contracting the disease from another, and it was extremely rare for both husband and wife to be infected. In seven out of

every 100 deaths of persons over the age of 40 the cause was cancer, so that there was scarcely a family of three generations without a record of the death of one member from this cause. The present increased general length of life accounted in some measure for the rise in the cancer death rate, as also did the greater accuracy of diagnosis in the last twenty years, but nevertheless the increase by 41 per cent. of the cancer mortality rate in this period was serious. Fear did not cause cancer, but it might prevent persons from applying for treatment until it was too late. Surgery and radium were both effective in many cases, and everything possible should be done to spread knowledge so that all suitable cases should be dealt with without delay. The primary objective of the British Empire Cancer Campaign was to ascertain the cause and promote the cure of this scourge. After the lecture Dr. Ronald Canti demonstrated his film of normal and abnormal cellular growth.

Work of a Child Guidance Clinic

Under the auspices of the Jewish Health Organization of Great Britain the East London Child Guidance Clinic was inaugurated in 1927, and Dr. Emanuel Miller, its honorary director since then, has now compiled a report of the work achieved during the first five years. As early as 1925 the organization had recognized an increase of psychological maladjustment among the children of Bishopsgate, and a simple beginning was made in three rooms with a staff of two psychiatrists trained in child pathology, a psychologist to perform mental tests, and the services of a special worker loaned by the Child Guidance Council. From the start there was a rapid flow of cases, and cordial co-operation was established between the new institution and school doctors and care committees as well as with social and philanthropic bodies in the neighbourhood. The report contains a survey of the lines on which the testing and treatment of children are conducted. Each child is submitted to an English adaptation of the Binet-Simon test, and a variety of performance tests are also employed. Tests of temperament and personality have been found to be of little value. The equipment has been extended to deal with children of pre-school age; the Merrill-Palmer scale has been found to be very useful in this connexion, bringing out such traits as over-dependence, distractibility, and negativism. Evidence has accumulated to show that mental retardation, or special linguistic or arithmetical disability, may engender a severe feeling of inadequacy with consequent emotional disturbance. On the other hand, intensive clinical work has revealed that emotional difficulties have the widest repercussions on all phases of the child's mental development, including scholastic achievement. It is significant that over 30 per cent. of the cases referred for treatment on account of general backwardness have been found to be normal or above normal in intelligence. Psychotherapy, coupled with remedial tuition, can do much to alleviate such maladjustments. Of the total number of cases referred to the clinic 288 were Jewish, 278 non-Jewish, and six the offspring of mixed marriages. Of these 572 cases 364 were boys and 208 girls. The excess of boys over girls has been a constant feature during each of the five years. There were 238 cases of psychoneurosis (nearly half of which were referred by school doctors), 158 described as unmanageable, uncontrollable, and cases of temper, fifty-nine of theft, sixty-five of backwardness at school, twenty-seven of sex difficulties, fourteen of failure at work, and eleven referred for wandering. In an appendix on cases followed up for one and a half to two years after discharge it is noteworthy that in many instances one or other parent required psychotherapy or had been an inmate of a mental hospital.

Reports of Societies

POST-MENOPAUSAL HAEMORRHAGE

At a meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine held on February 16th, with the president, Professor W. BLAIR-BELL, in the chair, Mr. V. B. GREEN-ARMYTAGE read a paper on post-menopausal uterine bleeding.

He stated that the clinical material upon which his paper was based consisted of 304 cases seen by him since 1924, both in Calcutta and in London. He defined the menopause as that period of a woman's existence six full months after the cessation of the normal catamenia. For the purpose of an analysis of the cause of the bleeding he divided his cases into: (a) visible, of which there were 140 instances; and (b) invisible, of which there were 164. The percentage of malignant causes in the first group was 31.4, and in the second 39.6. Dealing with the latter group, in which the cause was not external, Mr. Green-Armytage discussed those cases in which the bleeding had not resulted from obvious neoplasms, and was separate from disturbances in the endocrine system. He speculated upon the nature of the changes in the co-ordinated system of internal secretions which occasionally resulted in a resumption of ovarian activity after complete cessation at the climacteric. In connexion with a series of cases of "metropathia haemorrhagica," he insisted upon the necessity for close co-operation between the clinician and the biochemist with his laboratory facilities. Passing to the cases of bleeding associated with neoplasms of the ovary, Mr. Green-Armytage observed that in only a small proportion of the cases was the neoplasm innocent. He recalled that in a personal record of 547 ovarian tumours published in 1931 sixty-three occurred in patients past the menopause, and of these four innocent and twenty-six malignant cases had symptoms of uterine haemorrhage. The hypothesis was advanced that an ovarian tumour in a woman after the menopause may take on the function of the original ovarian tissue, just as after thyroidectomy for cancer metastatic tumours have been known to function like the original thyroid gland. Experimental evidence in support of this theory was advanced. Mr. Green-Armytage presented several specimens, and showed on the screen a number of photographs of uteri which he had removed. Discussing treatment, he emphasized the necessity of laparotomy in cases of uterine bleeding associated with ovarian tumours, but asserted his preference for removal of the uterus by the vaginal route in cases not complicated in this manner.

Professor MILES PHILLIPS said that in preparing such an analysis it was necessary to decide exactly when the post-menopausal era began. Whereas Mr. Green-Armytage had allowed six months to elapse, Dr. Fahmy, in a similar analysis, had allowed the more satisfactory period of twelve months to elapse since the last regular menstrual loss. This might explain the surprisingly large proportion of cases in this series in which bleeding was due to uterine fibroids. In his experience bleeding from this cause might occur in the intramenstrual epoch, but seldom after the menopause was established; on the other hand, cancer of the corpus uteri, though most commonly menopausal, was also intramenopausal, and never antemenopausal in its incidence. Professor Phillips considered this a useful distinction in reminding the medical attendant of the possible causes of bleeding at this dangerous epoch of a woman's life. Professor BECKWITH WHITEHOUSE quoted clinical evidence to prove that some of the cases of post-menopausal bleeding were related to delayed ovulation. He also discussed the formation of simple adenomatous polypi in the uterus.

Mr. GREEN-ARMYTAGE, in reply, said that he laid particular emphasis on a period of six months' amenorrhoea. Although twelve months was perhaps the best physiological limit, he considered it advisable, from the point of view of the practitioner, to adhere to a six months limit. With regard to the criticism that the number of

cases of fibroids in his series was abnormal, he pointed out that Howard Kelly, himself, and others had observed the greater frequency of these tumours in hot countries and in coloured races.

Vaginal Hysterectomy

Mr. M. DATNOW read a paper on vaginal hysterectomy, and illustrated the technique by means of lantern slides and a cinematograph film.

He referred to the history and the development of the operation, and went on to describe the advantages of vaginal hysterectomy when there was a choice between this and abdominal hysterectomy. There was less shock and a more rapid convalescence, while drainage was better. The absence of an abdominal scar had a good psychological effect upon the patient, and obviated the risk of incisional hernia. Prolapse operations could be combined with the hysterectomy, and the post-operation care of vaginal hysterectomy patients was simple. The only contraindications were: (1) a uterus that was too large to be delivered through the vagina, and (2) fixity of the uterus. In carcinoma of the body of the uterus Mr. Datnow considered it a better surgical procedure to remove the uterus by the abdomen. Among the reasons for employing vaginal hysterectomy were: (1) bleeding uterus, especially where there was prolapse as well, with (a) multiple small fibromyomata, (b) chronic subinvolution with cystic ovaries, and (c) polypi after the menopause; (2) obesity of the patient; (3) the presence of skin disease of the abdominal wall, and burns, or of a colostomy wound; (4) inversion of the uterus; (5) septic uterus after criminal abortion; (6) carcinoma of the body of the uterus only in certain special cases; and (7) advanced age—old people stood vaginal better than abdominal hysterectomy. Twelve stages in vaginal hysterectomy were described, and Mr. Datnow illustrated the procedures which facilitated each stage. He concluded by giving a composite table of cases that had been operated upon by Professor Blair-Bell and himself.

In the discussion, Mr. A. C. PALMER agreed generally with Mr. Datnow with regard to the indications for vaginal hysterectomy. He did not consider nulliparity a contraindication, and demonstrated by a diagram how it was possible to increase the dimensions of a narrow vagina by means of a posterior incision. He proclaimed himself a firm believer in vaginal hysterectomy for genital prolapse, because he had found that a large proportion of women suffering from "prolapse" complained of excessive or irregular bleeding. There were forty-seven such cases in his series. He also emphasized the satisfactory manner in which associated hernial protrusions, such as cystocele, rectocele, or enterocele in the pouch of Douglas, could be cured by appropriate plastic measures combined with vaginal hysterectomy. The steps of the operation which he was accustomed to perform were demonstrated on the screen by means of a series of drawings. Mr. Palmer maintained that any uteri not larger than a foetal head and not adherent to ovarian tumours or to bowel were suitable for vaginal hysterectomy.

Professor PHILLIPS said that he had been brought up to use the vaginal route for the removal of the uterus whenever practicable. He had performed 660 vaginal hysterectomies with thirteen deaths, and he considered that with the improved technique of recent years mortality had been further reduced. All his last 102 private cases had been successful. The obese and the "poor subjects for operation" were best dealt with by vaginal hysterectomy. There was less shock, less pain, and easier after-nursing than after abdominal operation. He had for many years advocated the operation for the cure of genital prolapse in certain conditions, of which he mentioned the following: associated early carcinoma of the corpus, and certain conditions of the cervix which rendered it unsuitable for amputation, such as deep lacerations and stenosis with pyometra. Additional advantages gained were the cure of accompanying hernia into Douglas's pouch and the cure of varicoceles in the broad ligament, which were the cause of disappointment after otherwise

successful double colporrhaphy. Professor Phillips gave a detailed description of his method of operating. Points upon which he laid particular stress were that he usually made his first opening into the peritoneum through the posterior fornix; he used catgut of the unhardened variety; he usually removed the uterus first and dealt with the appendages afterwards. He occasionally found it advantageous to split the uterus vertically, and he often used the Trendelenburg position to keep bowel away from the field of operation.

Professor BECKWITH WHITEHOUSE felt that the method under discussion had been too generally supplanted by abdominal hysterectomy in Great Britain and America. Fraenkl of Vienna still regarded it as the method of choice. Radium therapy had largely taken the place of hysterectomy in the treatment of uterine haemorrhage, but there still were an appreciable number of hard fibrotic and painful uteri which bled from an atrophic endometrium for which radium was unsuitable. In this type of case he found vaginal hysterectomy entirely satisfactory. The speaker made special reference to Werner's method of bisecting the uterus before the removal of each half separately. Mr. GREEN-ARMYTAGE said that he had performed 329 vaginal hysterectomies with only four deaths, and he preferred it for the majority of those cases of benign haemorrhage which were in many clinics treated by radium. Radium sometimes failed, was often followed by discharge and pruritus, and was liable to produce cancerphobia. As regards technique, he had gained considerable benefit from diminished oozing by adopting Danforth's procedure of injecting pituitary extract into each paracervical plane before making an incision. Mr. W. W. KING regarded vaginal hysterectomy as the operation of election. His cases at the Jessop Hospital for Women had numbered 539 with twelve deaths. He saw no necessity for removing the Fallopian tubes in every case.

DIAGNOSIS AND TREATMENT OF BRAIN ABSCESS

At a meeting of the Section of Otology of the Royal Society of Medicine on March 2nd, with Dr. W. J. HARRISON in the chair, a discussion took place on the diagnosis and treatment of brain abscess.

Mr. HUGH CAIRNS (with whose remarks Mr. C. DONALD was associated) said that a chronic abscess of very long duration almost invariably had a wall of hyaline fibrous tissue $1\frac{1}{2}$ cm. or more in thickness. This group included abscesses which had been imperfectly drained on a previous occasion, and also abscesses which had been clinically latent for long periods. Abscesses of this type could not be treated successfully by drainage, because the thick wall of hyaline fibrous tissue would never collapse completely or be entirely absorbed, and abscesses of such chronicity had a strong tendency to loculation.

He recalled a case he saw when working with Harvey Cushing in Boston, of a girl with abscess following frontal sinus infection. The abscess had been drained, but continued to discharge intermittently. The patient had a bulging hernia covered by skin (it was called "hernia" when covered by skin, and "fungus" when not so covered). Cushing opened the site of the sinus and gradually enlarged the incision, then got hold of the capsule of the abscess and pulled it out. On dissecting out the abscess, which was about 5 cm. in diameter, he found two more abscess cavities behind, lined with rather thicker walls, going back 9 to 10 cm. into the brain from the site of the old sinus. The speaker described the magnificent operation whereby Cushing, finding it dangerous to work at such depths through a small opening, was able to pull the capsules forward and "marsupialize" the abscesses.

It was doubtful, Mr. Cairns continued, whether abscesses should be operated on in the acute stage, but occasionally this might have to be done. The treatment of chronic abscess was to leave the wall of the abscess alone and drain the cavity. One must be prepared to explore over a wide field. If the patient was a male the whole of the skull should be shaved if there was time for it,

because it facilitated dressing afterwards. On getting into the abscess its depth was measured, the brain needle being graduated, and by gentle manœuvres its extent was estimated. If the needle went in very obliquely it was much better to withdraw it and make another hole at a place where the abscess might be nearer the surface. After the abscess had been encountered at a favourable site and its depth was known, a rubber catheter was taken and silk tied round it 1 cm. below the depth to which it was desired the catheter should go, otherwise the sense of distance was apt to be lost. While the catheter was being got ready the needle was withdrawn, and the bony opening enlarged to 2 or 2.5 cm. The dura was then opened more widely and the catheter gently passed into the brain. It would go easily into the soft brain tissue which always surrounded the abscess. After the catheter entered the abscess, as shown by pus in the lumen, it was left *in situ*, cut off 2 cm. above the level of the scalp, and dressing applied. Gauze sterilized in paraffin or vaseline was the best dressing, and this was piled up above the level of the catheter. Sometimes the catheter would not go through the abscess wall. If the condition of the patient was not extremely urgent it was best to leave the tip lying against the wall of the abscess for a few days, doing nothing more. Then, when the next dressing was done, the catheter would be found to have produced some erosion on the abscess wall, and it was possible to get in. If the patient's condition was urgent, so that immediate drainage was necessary and the catheter could not get in, a firmer catheter was tried, strengthened perhaps by a stylet. If the abscess was very deep-seated and the catheter would not enter it, the next best thing to do was to leave the brain needle in place. With regard to drainage by direct vision, as opposed to "blind" drainage, this might be through a limited opening or through an osteoplastic flap. For the former it was necessary to have an opening in the skull at least 3 to 4 cm. in diameter. After the pus was found with the needle the cortex was excised and some special form of retractor passed down into the abscess. Stress was laid on the importance of the passing of the drain down into the depths of the abscess cavity. The speaker's own feeling about this type of operation was that it was satisfactory when the abscess was superficial, but there were serious objections to it when the abscess was deep-seated. The opportunity for inspecting the abscess cavity might be very fleeting, and everything had to be done so rapidly that there was no room for any hitch. Just at the moment of exposure of the abscess the field might be obscured by fresh bleeding from the cortical vessels by the deeper and stronger retraction which was necessarily, though unconsciously, made at that moment. With regard to drainage through an osteoplastic flap, he had done four cases in that way, and three of them had recovered. He did not advocate it as a routine method, but experience showed that it could be employed in certain difficult cases with remarkably little risk of meningitis.

The after-treatment of acute or chronic abscess was the same whatever method was employed in draining the abscess. Dressing should be done only at long intervals. The first dressing was left undisturbed for as long as possible, usually a week, sometimes ten days. The dressings were done in the operating theatre, and by the surgeon who had drained the abscess, and usually from half to three-quarters of an hour was allowed for them. The tube was not removed, except when intracranial pressure suddenly pushed it out when the dressings were taken off, and this they endeavoured to avoid. The next important factor was prolonged rest in bed. As to complications during after-treatment, rise of temperature was almost invariable. A large number of brain abscess cases had a normal or subnormal temperature before operation, and after the release of the pus the temperature went up. The really important complication after operation was post-operative oedema—this had occurred in several of his cases, both those drained by the open method and by catheter. In one of his flap cases it was necessary to re-elevate the flap within twenty-four hours, and the whole brain could be seen to be very much swollen.

although the abscess had not recurred. It was not known why the oedema was present, but if the tube had gone well into the abscess cavity the right thing was to leave the patient alone and not interfere. Squints seemed quite common after abscess, but apparently they were not of serious import; the patient appeared to have a little basal meningitis. In three of his cases there were fits during the first weeks of convalescence, and one patient still had them. Undoubtedly epilepsy might be a disappointing complication of brain abscess otherwise successfully treated. It had nothing to do with the treatment, he thought, but was connected probably with the previous disposition of the patient.

Mistakes in diagnosis were much more frequent causes of failure than mistakes in surgical procedure. He emphasized the frequent slightness of the headache in brain abscess. It might be common at the onset, but superseded by lethargy and drowsiness, a condition which tended to make doctors and nurses less anxious. Another mistake arose out of the notion that absence of papilloedema excluded a diagnosis of abscess; it could not be too widely known that some cases had no swelling of the disks at all. He also emphasized that in lumbar puncture only a minimal amount of fluid must be taken. Other cases in which the diagnosis was interfered with were those in which extradural and subdural abscesses occurred, and these were thought to be sufficient to account for the symptoms, so that the brain was not explored. It ought to be possible to say before operation whether the case was one of intracerebral disturbance or extradural abscess. In 109 cases of brain abscess at the London Hospital secondary to otitis media and mastoiditis there were six in which the abscess was not temporal, but occipital, parietal, or frontal; seven out of the 109 cases were multiple temporal and cerebellar on the same side. Many of the difficulties of diagnosis could be overcome by careful history-taking and neurological examination. He specially stressed the importance of examination of the visual field. That was an examination which could not be done after the patient became lethargic. When intracranial complications were suspected neurological examinations should take precedence over mastoidectomy, because these would reveal more as to what was happening inside the dura.

Mr. SYDNEY SCOTT said that all had witnessed gratifying results in the treatment of brain abscess, but even given the resources of modern surgery, the prognosis must be extremely grave. Recovery depended not only on the skill of the operation, but on the mysterious production of antibodies, and, though the infective agent could be isolated and identified, knowledge of how to control its activities was far from precise. The essential treatment, however, at present was surgical. It was possible occasionally, and sometimes necessary, to enucleate the abscess in its entirety, without liberating its contents. When this was impracticable, resort must be had to evacuation and drainage. In chronic middle-ear disease the so-called radical mastoid operation should be performed in every case. The fact that middle-ear disease might have cleared up completely was very misleading, especially to physicians who might be called in because the patient had headache or vomiting weeks afterwards. He had seen many cases left unrecognized on that account until very late. With regard to exploration, someone had called the finger a clumsy tool, but digital exploration, he thought, was justified, and without it many abscesses would have been missed. A curious feature of brain abscess was its variety, not only in respect of pathology, but in the character of the walls, the size, and the symptoms and signs. Of special value were transient signs, such as wrist-drop lasting a day or two, a little lower facial palsy on the opposite side, or a transient ocular paresis. Optic neuritis, he thought, was rare in brain abscess, but one of the most marked cases of extradural abscess he had seen had haemorrhages and optic neuritis. As for after-treatment, a week should certainly be allowed to elapse before another dressing was done, and the less interference after the evacuation of the abscess the better.

Sir CHARLES BALLANCE said that he had no recent experience, and therefore no right to take part in the discussion, but he had attended in order to learn how much progress had been made in treatment, and he had been greatly impressed by the remarks of the two previous speakers. They would all agree that a brain abscess was a tumour, and that the ideal treatment was excision. He remembered in the distant past a brain abscess which he had excised and which had a wall so thick that the abscess could be rolled about on the floor like a billiard ball. There was no treatment for such a tumour except excision. As for the finger being a clumsy instrument for the discovery of brain abscess by palpation, he claimed that his own finger was the best probe ever invented. Brain abscesses had been missed because careful, complete, and repeated neurological examinations had not been made. Diagnosis and treatment would be much better if the need for such examinations were constantly borne in mind. A case of brain abscess secondary to temporal bone disease was not two separate processes of disease, but one continuous process in almost all cases. That being so, the surgeon ought to be able to follow the disease from the temporal bone through the meninges into the brain, and he himself had done this on many occasions. If that were done, and the abscess drained, the patient would be cured and exposed to no risk of meningitis. He would not imply that this could always be done, but he had done it many times in the temporal region, and also when there had been an abscess in the frontal bone. He agreed with Mr. Cairns that all subsequent dressings should be done by the surgeon himself.

Mr. F. C. ORMEROD spoke against the use of theallet in operation. He thought that injury was done by the hammering of theallet on the mastoid process within an inch or two of the wall of the abscess cavity. In a case of temporo-sphenoidal lobe abscess which he brought before the Section a large area of bone had been removed from the temporo-parietal area by means of bone forceps, theallet not being used at all. A large abscess was discovered by means of a Record syringe and needle, and was opened by an incision through its lateral wall. Convalescence had been uneventful.

Mr. MILES ATKINSON stressed the fact that in many of these cases localizing signs were not obtained until very late in the history of the disease. There were general signs of brain abscess, particularly headache, but no localizing signs; this applied even to the cerebellum. The localizing signs depended, he believed, upon the oedema. If the abscess was of a fairly chronic type, with not a very thick wall, there was not a great amount of surrounding oedema, and therefore localizing signs were not forthcoming. It was a mistake to wait for localizing signs before exploring the brain. Transience of signs was almost a diagnostic point: a sign "here to-day and gone to-morrow" was of very great help. Once a brain abscess had been drained it should be left severely alone. That was partly why Macewen got his high percentage of successes. Meddlesome surgery, too frequent dressings, washing out with antiseptics, and packing with gauze, all tended to produce the very thing it was desired to avoid. Dr. W. J. HARRISON mentioned the value of finger exploration; he had found secondary abscesses by using the finger to explore the temporo-sphenoidal lobe. Mr. J. A. GIBB asked whether Mr. Cairns would propose a larger opening with free incision of the dura mater, in view of the possibility that the abscess, if it had been missed, would tend to come towards the opening. Mr. HUGH CAIRNS, in reply, said that the making of a larger opening all depended on what was found with the needle. Deep-seated abscesses were best treated by close drainage, but with a surface abscess a larger opening could be made. The main reason why the scalpel had been given up was because one counted so much on finding the resistance of the capsule, but once the abscess had been reached a fine scalpel used gently might be of service. On the whole question he considered that, providing the surgeon had a clear idea of what he wanted to do, and handled the brain gently, the battle was won or lost at the bedside.

FUNGUS INFECTIONS OF THE SKIN

At a joint meeting of the North London Medical and Chirurgical Society and the City Division of the British Medical Association, held at the Royal Northern Hospital on February 28th, with Dr. P. O. ELLISON in the chair, an address was given by Dr. HENRY C. SEMON, physician for diseases of the skin at the hospital, on "The Alarming Increase of Fungus Infections of the Skin and a New Outlook on their Treatment." Dr. Semon said that he was not responsible for the title announced for his address, but the CHAIRMAN claimed, after Dr. Semon had spoken, that it was thoroughly justified by the facts he brought forward.

Dr. Semon began by demonstrating illustrative cultures of the three main groups of pathogenic fungi responsible in this country for most cutaneous mycelial infections in man—namely, the microsporon, the trichophyton, and the epidermophyton. The *Microsporon audouinii* was the chief cause of ringworm of the scalp in children, and was pathogenic to man only. Another microsporon was derived from animals, mostly cats, and might also infect the scalp. He was concerned, however, with the other two groups, and more especially with the symptoms due to the epidermophyton, which, so far as was known, was peculiar to man and not found in animals. This fungus might infect the skin and the nails, but never the hair, whereas the trichophyton, which was frequently derived from animals, could infect all three. The total number of probable epidermophyton cases seen in three out-patient clinics and in private practice during a recent six months was much greater than had been observed in previous years, and exceeded for that period of six months the infections due to scabies, pediculosis, and impetigo taken together. The symptoms in these cases were maceration and peeling of the skin between the toes—especially the fourth and fifth—development of fissures and painful cracks, spreading of erythematous and scaly conditions on the soles, and the local development on the insteps and legs of associated follicular irritation and scaly and eczematous patches. The toe-nails not infrequently shared in the infection. The infection might spread by contiguity, or might be conveyed to a distance by bath towels—as, for example, to the groins (dubie itch) or to the internatal cleft and crutch, where it might give rise to an intractable form of pruritus ani or pruritus vulvae. There was conclusive evidence to show that once the susceptibility of the skin to the fungus had developed, various symmetrical eruptions could occur at a distance, and the infection itself might be conveyed by the blood stream. The commonest of these eruptions was the so-called "dysidrosis," in which great discomfort, irritation, and peeling between the fingers and on the palms was produced. A form of palmar exfoliation noted during the summer months of the last two or three years, without any vesiculation, might conceivably be caused in this way. While the foot infection usually preceded the hand infection, the reverse might occur, and a circular or circinate tinea patch, usually on the thenar eminence, might prove the herald of constantly recurring eczematoid trouble in that situation and on the feet. It was important to differentiate the primary foci of infection from the secondary, as the former must be attacked vigorously in treatment, while the latter seemed to obey the same laws as eczema due to other causes. The principal means of differentiation was by culture. Primary untreated foci always contained mycelium. Secondary infections very rarely. While a member of the epidermophyton group was usually responsible for this infection, certain of the trichophyton group could produce similar manifestations.

Dr. Semon went on to mention a classical experiment by Peck, who infected a patient (who had volunteered for the experiment) with the mycelium of the epidermophyton between the toes of both feet. Itching and irritation with local vesicles developed four days later, on the thirteenth day the specific trichophytin reaction previously negative was found to be positive, and on the twenty-fourth day a typical dysidrosis or cheirpompolyx eruption, with itching, developed in the clefts between the fingers of both hands. Dr. Semon thought that the significance

of that complication ought to be realized, for the aetiology of dysidrosis of the fingers—one of the most common affections of the skin in the summer months—was seldom ascertained, and once in his experience had been ruled by a medical assessor in a court of law, who was not a dermatologist, to be due to nervous influences. Peck's suggestion that the term "epidermophytid" should be used for the interdigital vesicles and other eczematous manifestations which might develop in the course of the foot infection deserved general support. Another point of great interest in Peck's experiment was that, after a complete clinical and bacteriological cure of his artificially infected patient, he reinfected her and obtained a more violent response in exactly the same areas, with pronounced accentuation of the trichophytin reaction, thus showing that, unlike what occurred in certain trichophytin infections, immunity had not been achieved. He had dwelt upon Peck's experiment because it was an artificially produced replica of the common case of eczematoid ringworm of the extremities met with in general practice, and illustrated most of the reactions and complications that could occur in the course of the infection. To these must now be added yet another—namely, the eczematoid—by which was meant the occurrence of vesicular or scaly, usually circular, patches of dry or weeping dermatitis, which might or might not itch, and from which the fungus could seldom be recovered. This manifestation was by no means uncommon, and its recognition would further diminish the category of eczematoid of doubtful causation. Of very great interest also was the "eczema marginatum" of Hebra, now termed "tinea cruris" or "dubie itch," which was due to the conveyance of this fungus from between the toes to the toe-nails, and, by means of towels, to other parts of the body. It was a true secondary infection, containing mycelium, and was not to be placed in the same category as the allergically produced dysidrosis or eczematoid patch, which might be termed "epidermophytids."

PREVENTIVE AND CURATIVE MEASURES

The realization of these facts (Dr. Semon continued) should stimulate prophylaxis, and he welcomed this opportunity of drawing attention to what he regarded as the most important and almost universal factor in the production of a pedal mycosis—namely, the standard boot or shoe. Rationally considered, the boot was nothing more or less than a leather incubator. All the necessary conditions—heat (at 39° C.), moisture, and darkness—were provided, and the culture medium was the human epidermis. Too much stress, in his opinion, had been laid upon the external sources of the infecting agent, such as bath mats, towels, and the bathing boxes of swimming pools, which might, of course, harbour the fungus from previous users or occupants, but could never operate if the footwear conditions were not so favourable. An ideal measure would be the adoption of the Roman sandal, which would permit the free passage of air and light between the toe clefts, and thus create an unfavourable soil for the spread of mycelium. He had seen a complete clearance of the condition after three weeks by this simple procedure alone in a case of many years' involvement of the outer clefts and the soles of both feet.

The local applications recommended for the elimination of this pest were many. The best known was that devised by Whitfield—an ointment of 3 per cent. salicylic and benzoic acids—which bore his name. This was exceedingly useful in the chronic peeling types, and should be rubbed in at least once daily, on a finger-stall, to avoid infection of the fingers and finger-nails. Some American workers aimed at thorough decortication by salicylic acid or other peeling agent, but even by this radical procedure a permanent cure could never be guaranteed once the mycelium and its associated allergy had become established. Castellani's carbolfuchsin and resorcin paint was of special value for the pruritus ani and vulvae due to secondary infection in the groins and crutch, and some cases of eczematoid type did well on

a paint of 1 per cent. gentian violet in 25 per cent. spirit, applied daily with a brush and protected with an indifferent dusting powder or Lassar's paste. Silver nitrate in from 0.5 to 2 per cent. solution with spirits of nitrous ether was also found useful in the eczema group, but the important point was to eradicate the primary infecting focus, when this could be recognized, between the toes. The treatment of the acutely inflamed case must be on general lines. Frequent applications of lead or 1 per cent. aluminium acetate solution, weak resorcin in borie lotion, calamine or 1 per cent. ichthyol lotions, and, in very purulent states, the potassium permanganate foot- or hand-bath, were well recognized and proved remedies. The inflamed skin should not be allowed to dry up, yet the heat of oiled silk protectors against evaporation inhibited their use. Butter muslin soaked in the prescribed lotion must be constantly renewed until, with the subsidence of the acute stage, oily liniments or pastes could be substituted. The epidermophytid of the fingers needed a drying treatment with weak salicylic (1 to 2 per cent.) spirit and calamine to encourage desiccation and the peeling stage, and the bullous types called for the evacuation under sterile conditions of serum and pus and the application of dressings similar to those already described for the acute condition. The tendency in all the acute cases was towards spontaneous involution and cure, and it was the chronic types and the frequent subacute and acute complications to which they were liable that caused so much disability during hot weather.

Discussion

The ensuing discussion took the form mostly of questions addressed to the lecturer.

The CHAIRMAN (Dr. Ellison) said that after hearing Dr. Semon speak he did not think any apology was needed for the title given to his address, because he had painted rather an alarming picture. Even if it was known that ringworm of the foot was common, it had not been realized what great mischief it could bring about. Anyone who had seen the nails on the hands and feet of people who had this infection were aware how very disagreeable it could be. It was possible that more was heard of it nowadays, but it seemed as if the cases had been greatly exalted in virulence. With regard to cultures, it was absolutely essential, if one was to identify the particular varieties of fungi, to have a standard culture medium, and one of the great disadvantages of Sabouraud's medium was that it was not always possible to get two successive batches of medium which would produce identical cultures of the organisms grown. Some years ago W. N. Goldsmith took that point up and brought out a new medium, but he had told the speaker that even then he was not satisfied, and he recommended a medium containing crude commercial glucose as being preferable to maltose. With regard to remedies proved useful in the infection which Dr. Semon had illustrated, he himself had found iodex ointment useful, but it left a disagreeable stain.

Dr. W. E. SNELL said that when he was medical officer at Colindale the so-called dhobie itch was seen to be very common among the male adult patients, so that it was made a rule that every patient must be inspected on admission, and he thought that about 50 per cent. of them were found to be infected. Dr. Semon said that that seemed to him a heavy percentage, and it was probable that some of the patients were suffering from erythrasma. This was a disease which copied dhobie itch but produced no symptoms, whereas dhobie itch, true to its name, always itched very severely.

In reply to Dr. KATHLEEN MATTHEWS, Dr. Semon said that he thought the large majority of dysidrosis cases were fungus infections, but it was extremely rare to recover the fungus. Even in Peck's case, which he had mentioned, the fungus was not recovered from the dysidrotic vesicles. These were reactions produced by the fungus at a distance, and they might be eczematous in character, taking the form of small discoid patches, or they might be vesicles. He added, in reply to other questions, that in an eczema due to the fungus it was necessary first to eradicate the primary focus and use strong salicylic

acid ointment. With regard to silver nitrate, which was mentioned by one member, he would not like to use the caustic stick, but a 1 per cent. solution was a very valuable remedy for the cracks and fissures. As to the treatment of nail infections, he thought a great deal of good could be done by taking an orange stick and dipping it in a strong salicylic ointment, and introducing it every day under the nail. The ointment should be applied well under the nail fold as far as it could be got.

In reply to a question on the hygiene of swimming baths, Dr. Semon said that, of course, it was a necessary hygienic precaution for each person to take his own towel, also to avoid standing on bath mats which were used by many people, and perhaps a little spirit might be taken and the feet treated on each occasion after bathing. He did not believe in water infection at all, certainly not infection in which fungus was concerned. Finally, he said that the infection of which he had spoken was a disease not of dirty people, but of clean people. Excessive use of soap and water, as was seen in laundry women, brought about a maceration of the skin, which gave the fungus its opportunity.

BLOOD REGENERATION IN TROPICAL AND NON-TROPICAL ANAEMIAS

A meeting of the Royal Society of Tropical Medicine and Hygiene was held at Manson House on February 15th, the president, Sir LEONARD ROGERS, being in the chair.

Professor A. E. BOYCOTT dealt with the regeneration of red corpuscles, especially from the experimental aspect, pointing out that after a serious haemorrhage leucocytes were restored in a few hours, platelets in two or three days, and red cells in several weeks. When a normal rabbit was bled about one-third it replaced its lost haemoglobin in about three weeks, the response being conditioned by the amount of erythropoietic tissue in the marrow rather than by the strength of the stimulus. The marrow was working to its utmost, and the time taken to regenerate a haemorrhage was proportional to the amount lost. When graphed the course of regeneration was seen to be a straight line; this was in contrast to the hyperbolic curve of restoration in pernicious anaemia, in which the supply of P.A. factor fired off an enormously hypertrophied bone marrow and enabled it to do effectively what it had been failing to do previously; here the marrow was quantitatively adequate if only it could get over the biochemical impediment to its proper activity. In normal animals, and with all the necessary materials for making new red cells at hand, the rate of regeneration depended a great deal on the species. Thus the rat regenerated blood three times as fast as the rabbit, which again probably regenerated it at a rate two or three times as fast as man. Calculating from the relative metabolic rates, man would take six to nine weeks to regenerate a blood loss of a quart, and six months if one-third of the original blood was lost. Age made a difference, as did also practice. Professor Boycott showed that if a rabbit regenerated a first haemorrhage in nineteen days it restored a second of the same size in seven days, and if frequent small losses recurred it soon acquired the facility for keeping its blood near a normal level. Hypertrophy of the erythropoietic tissue of the bone marrow occurred under such conditions, and the stimulus which roused the marrow to activity was actual shortage of red cells in the circulating blood. In rabbits a fall in the percentage of haemoglobin was at once followed by reticulocytosis, while transfusion of compatible blood reduced but never completely eliminated the reticulocytes, even though an artificial polycythaemia had been temporarily induced.

Dr. JANET VAUGHAN next reviewed the haemopoietic response to therapy in non-tropical anaemias, emphasizing that blood regeneration in anaemia due to haemorrhage, as well as in the dyshaemopoietic anaemias,

followed certain principles, provided adequate supplies of haemopoietic factors were present and inhibitory factors were absent. The character of this response was to a large extent supplied by the cause of the anaemia, and it could be analysed by a study of the response of the reticulocytes to therapy, and later by an estimation of the haemoglobin and red cells gained. In the megalocytic hyperchromic anaemias, due to lack of the P.A. factor, the peak of the reticulocytic response was inversely proportional to the red cell count before treatment. The figures for parenteral treatment might prove higher than those obtained in oral treatment, and it was also probable that the rate of red cell increase would prove greater in response to parenteral treatment. In the case of hypochromic anaemias responding to iron the number of reticulocytes at the peak of the rise appeared related to the initial haemoglobin level rather than to the initial red cell level. In estimating the expected reticulocyte rise, however, both red cell level and haemoglobin level before treatment had to be taken into account. The difference in the response to iron and liver was probably due to the fact that in the anaemias responding to iron haemoglobin was primarily at fault, while in anaemias responding to the P.A. factor cell stroma was deficient. The anaemia due to scurvy also responded to appropriate therapy, including pure ascorbic acid, by the outpouring of reticulocytes and subsequent increase in red cells and haemoglobin. The anaemia following acute haemorrhage responded in exactly the same way, provided adequate stores of haemopoietic factors were present in the body. Factors inhibiting the maximum and classical response to therapy were: (1) the presence of multiple deficiencies which were not at first recognized; (2) the presence of achlorhydria; (3) failure of intestinal absorption; (4) a raised blood pressure; (5) sepsis. Though much was known of the factors necessary for normal haemopoiesis and of the principles governing normal blood regeneration, the part played by inhibitory influences was still very little understood.

Dr. HAMILTON FAIRLEY confined his remarks to observations made on anaemias met with during the past four years at the Hospital for Tropical Diseases, London. Anaemias of megalocytic type were encountered regularly in sprue, occasionally in kala-azar, and rarely in malaria; in all cases the underlying cause appeared to be derangement of gastric function, to which defective HCl secretion not infrequently afforded an index. In sprue moderate reticulocytosis might follow the cessation of diarrhoea induced by adequate rest and high protein dietary; the response, however, was submaximal and blood regeneration correspondingly slow unless augmented by liver extract or some similar preparation in adequate dosage. The response then resembled that seen in pernicious anaemia, the reticulocytosis being inversely proportional to the red cell count. Marmite was only occasionally effective in sprue, and ventriculin proved less satisfactory owing to the tendency sometimes to prolong the diarrhoea. Little, if any, attention had been paid to the effects of specific drugs on blood regeneration. Charts from syphilitics artificially infected with *Plasmodium vivax* and from naturally infected cases of benign and malignant tertian malaria showed that the administration in adequate dosage of quinine and atabrin was followed in six to nine days by reticulocytosis and blood regeneration proportional to the degree of anaemia. Chronic malarial anaemia led to considerable hypertrophy of red marrow, which extended into the long bones, and once the parasites were eliminated the large amount of erythroblastic tissue which had been laid down responded by reticulocytosis and rapid blood regeneration. In monkeys experimentally inoculated with *P. knowlesi* massive infection resulted, and a rapid haemolytic anaemia developed in from six to ten days, which soon terminated fatally with or without haemoglobinuria. If life were prolonged by specific therapy intense reticulocytosis and rapid blood regeneration followed, a result partly due to anaemia resulting from the critical loss of corpuscles and partly to the destruction of parasites. Passing on to blackwater fever in man, a reticulocytosis of 20 to 30 per cent.

followed the initial intravascular haemolysis within eight or nine days; an important factor permitting haemopoiesis was the destruction of malarial parasites which almost invariably accompanied the haemoglobinuria. In the anaemia associated with amoebic liver abscess reticulocytosis and blood regeneration followed the injection of emetine, but if there was a secondary coccal infection the reticulocyte count might remain elevated until surgical drainage resulted in healing of the abscess cavity. The data contained in these haematological charts indicated that parasites exerted an inhibitory influence on the bone marrow, and that once the cause of the anaemia had been dealt with proliferation of the erythroblastic tissue followed, resulting in a temporary reticulocytosis and rapid blood regeneration. Persistent submaximal reticulocytosis in anaemia implied a persistence of inhibitory factors or of the cause giving rise to the anaemia, whether the cause was a bacterium, a parasite, or a deficiency factor.

Dr. L. J. WITTS referred to a remarkable case of blackwater fever recovering after multiple transfusions, and inquired why, in aplastic anaemia, transfusion with compatible blood had so little effect. Such a patient might receive three pints of blood weekly—an amount out of proportion to the amount of blood destroyed—yet the anaemia progressed. The bone marrow was a complicated organ on which many factors played. Of the most important they had heard that night, but there were others, and the polycythaemia occurring in basophil adenoma of the pituitary gland suggested that nervous or endocrine factors might affect regeneration. Arsenic and x rays also stimulated bone marrow to produce red cells and reticulocytes.

Dr. G. W. GOODHART said there was evidence that after blood loss women were more efficient at blood regeneration than men, and this might be because menstruation made them practise blood regeneration. After abortion, if sepsis were not present, women regenerated blood with extraordinary rapidity when left alone and treated with ordinary doses of iron, whereas in males with a similar degree of anaemia transfusion would certainly be indicated. Dr. Goodhart cited a case of pernicious anaemia with a high colour index which changed to a low one on intramuscular injections of liver though megalocytes persisted. He asked whether this was a common experience, and whether iron should be administered, also how often intramuscular injections failed where intravenous ones succeeded. In reply, Dr. VAUGHAN said there was nothing in favour of intravenous as opposed to intramuscular therapy with modern preparations. She had not seen a case of megalocytic hyperchromic anaemia become hypochromic with large cells persisting, and thought it might be an instance of idiopathic steatorrhoea. Iron should be given alone if the response was to be correctly interpreted.

Sir RICKARD CHRISTOPHERS asked Professor Boycott whether the time factor in the regeneration of the protein constituents of the blood had been worked out, and Professor LEDINGHAM inquired what was the basis of the increased rapidity of blood regeneration after a second bleeding, and whether there was any factor other than a response to lack of oxygen.

Professor Boycott replied that the blood proteins regenerated in five to six days. To Professor Ledingham's question he did not know the answer. If, however, one asked an animal to do anything which it had not done before, it would always do it better a second time, and blood regeneration after haemorrhage was no exception to the rule; the marrow itself was probably also more active. In epitomizing the whole subject Professor Boycott said there were two main groups of cases to consider: one in which the response was limited by the quantity of marrow, as after sudden haemorrhage, and the other group in which the quantity of marrow had hypertrophied owing to lack of oxygen, and was adequate up to a certain point, but could go no further. Here two factors were involved: one, the materials necessary for the manufacture of blood, and the other, the extraordinary thing Dr. Fairley had told them about—namely, parasitic inhibition of marrow activity.

CORRESPONDENCE

Silicosis and South Wales Colliers

SIR,—I should like to add a few words in connexion with your accounts of the discussion on silicosis at the two recent meetings of the Institution of Mining and Metallurgy.

A matter which was not discussed at the meetings was why it is that so large a number of certified cases of silicosis occur among South Wales colliers. If these cases are real some explanation of their great frequency is needed, and Dr. W. R. Jones maintains that his sericite theory fills the gap. I need not repeat the reasons which to me personally seem conclusive for rejecting the sericite theory, but I should like to add here that after careful inquiry into working histories and clinical symptoms of a large number of the certified cases I find myself unable to accept the great majority of the diagnoses of the medical boards. Cases of silicosis in the sense commonly accepted end nearly always in death from phthisis, and if there were actually a large number of cases of real silicosis in this sense among South Wales colliers their phthisis death rate would be considerably increased above a normal figure. Actually, as shown by the Registrar-General's occupational mortality figures, the phthisis death rate of South Wales colliers is, like that of colliers elsewhere, considerably lower than that for the average occupied males. This seems to me inconsistent with the diagnoses of the medical boards, and whatever these diagnoses may mean they consequently cannot be accepted as of real silicosis, except in the comparatively few cases where serious exposure to dust from highly siliceous rock has actually occurred.

There seems to be no sound reason for believing that many more cases of real silicosis occur among South Wales colliers than among other colliers, and I think that the widespread alarm produced in the South Wales colliery district by the numerous certified cases of silicosis has no substantial basis so far as silicosis is concerned, though I hope it may have the effect of hastening a carrying-out of the precautions which are essential whenever it is necessary to drive underground roads in highly siliceous rock. The cases of silicosis from neglect of these precautions are so few that they do not affect appreciably the low phthisis death rate of the miners; but they are undoubted cases of real silicosis, and every effort should be made to prevent them.—I am, etc.,

Oxford, March 3rd.

J. S. HALDANE.

Pathogenesis of Cancer

SIR,—I have read with much interest the letter on the above subject in your issue of February 24th, by my friend Mr. Frank T. Paul. As corresponding colleagues at the Liverpool Royal Infirmary I saw many of his cancer cases, and was well acquainted with his views on the subject, which were of a very practical nature, but, unlike the present-day practice, did not lead to much lucrative work. This readily met with the approval of one who was more devoted to prevention than to cure. On one occasion Mr. Paul scraped out a small sebaceous gland from my neck, which he said was better removed lest it should develop into cancer. I said that I had no more dread of cancer than I had of the plague, and as the latter was non-existent in England the risk was negligible; however, it was interfering with my razor—not Occam's razor—each morning. I wished it removed, and the cure has been permanent.

Long before Mr. Paul had lessened the number of his operations for cancer of the breast I had formed the opinion that at least 75 per cent. of the operations on

the breast for supposed cancer, or a tumour which, if left alone, would or might become cancer, were simple cases of mastitis which, if treated with tincture of iodine and thyroid, would disappear. As practically all cases of cancer, wherever situated, are deficient in calcium the iodide of calcium was, and is, a favourite remedy with me.

Many years ago I asked the late Dr. Ernest Glynn for a specimen of cancer about which he had no doubt, though I did not care from which organ it came, and he sent me a whole breast which had just been removed. A few days afterwards I called to tell him that I could find no evidence of malignancy, and he told me that he had discovered the fact, but he had been let down by the surgeon, as, he regretted to say, often happened.

Some years ago I saw the wife of a medical man, in one of my periodic visits to this island, who had a small lump in her left breast, which I told him was, in my opinion, a simple case of mastitis that under a prolonged course of treatment would get quite well, but if he had any anxiety in the matter I would recommend him to consult an eminent surgeon in London, whom I specified, as I felt confident he would not operate unless he considered it absolutely necessary. They took the latter part of my advice, but unfortunately the eminent surgeon sent her to a radium expert, who applied a few radium needles and the lump melted away, which, in my opinion, was proof that the lump was non-malignant, and if the expert had then held his hand as would have been well; but not content with well-enough he apparently wished to do his job thoroughly and gave such a dose of radium that the whole breast swelled up to such an extent that it had to be completely removed. The lady was so exhausted that further treatment was deemed inadvisable for a time, but after a prolonged rest she began to recuperate, and then a course of deep x-ray therapy was prescribed for an imaginary secondary deposit in the right lung; but why the cancer should have jumped from the left breast to the right lung was not explained. This was simply a recurrence of a bronchial attack with slight pulmonary collapse, from which she had more or less suffered for a long time, due to excessive cigarette smoking. However, the deep x-ray therapy was carried out so successfully as to prevent the finishing touch to an unpaired life, but the operator sent her home before he was required to sign the death certificate. The husband of the lady thought that the wife of a medical man was not sufficiently profitable to interest my eminent surgeon.

I have not altered my opinion as to the nature of the affection—I will not call it disease—but I have often quoted the case to those who contemplated radium and deep x-ray treatment. I have also given my opinion as well as that of the husband, to my eminent surgeon which, I hope, will teach him that early and frequent operations, either with the knife, radium, or deep x-ray are not the only and best way of preventing the evolution of cancer.

I have no doubt that Mr. Paul will recollect my plan of preventing pneumonia after operations on the tongue and mouth for cancer. For about a week before any such operation is undertaken the patient receives, three daily, 15 grains of chloride of calcium, the mouth is frequently rinsed with a good antiseptic or pure alcohol, as recommended by the late Jonathan Hutchinson, but the patient is cautioned against swallowing the mouth-wash. For three days before the operation the patient receives each day a hypodermic injection of 10 c.c.m. of anti-streptococcus serum.

When vaccines came into vogue I wished Mr. Paul to try an autogenous vaccine, but he replied that he had never had a death from pneumonia since he adopted my preventive treatment, and he was quite content with a success of 100 per cent. I quite agree with Mr. Paul that although operations may be a very profitable method of treatment for the surgeon, from the patient's point of view we could eliminate many operations, and practise more preventive medicine.—I am, etc.,

St. Helier, Jersey, March 1st.

JAMES BARR.

SIR,—Mr. Frank Paul's letter on the above subject in your issue of February 24th contains nothing new, but it serves the very valuable purpose of inducing us to retrace our steps, and making us wonder whether, in our haste, we have missed one or two fundamental points. Suppose we go back to the very beginning and "think in protoplasm." Evolution may, and does, bring about differentiations in the protoplasm, but it cannot alter its organic constituents, which, through countless ages, remain the same. Growth is just a constant breaking down and building up of the protoplasm, which owes its instability to the contained nitrogen. All bodies into the composition of which nitrogen enters are most unstable—one has only to think of high explosives.

I think we all agree that growth depends on the amount of chemical change—that is, on the degree of instability of the protoplasm, which, in its turn, is regulated by the amount of nitrogen it contains. It is a fact that cancer appears more frequently in tissues formed of highly compounded nitrogenous molecules, where changes are most active, while tissues like fat, which consist of relatively simple molecules, and are thus the seat of little change, are passed by. There is thus something to be said for the belief of Mr. Paul and others, that the too free use of stimulating meat food may predispose to cancer. On the other hand, a healthy gastro-intestinal apparatus may be trusted to look after an excessive intake of proteins, which are broken down into amino-acids. From these cleavage products the cells take the necessary protein peculiar to themselves, the remainder being changed by the liver cells into harmless urea.

Now the nitrogenous body which is concerned in endogenous tissue metabolism is creatinine (*κρεατιν*—meat), a substance which is known to stimulate growth. Its amount may vary in different animals and individuals, but is remarkably constant. But one may ask, Why is it, when cancer develops, that it is only the cells of a particular organ, say the mamma, that respond to the nitrogenous whip? It is because the cells of the tissue affected have been kept young and more active by repeated irritation, and it is only young cells that are stimulated to greater effort by an excess of nitrogen. The farmer never gives sulphate of ammonia to mature plants, but to those which are young and growing. I sometimes indeed wonder whether the occurrence of cancer is a ghastly attempt on the part of the organism to reproduce itself asexually, after the functions of the true sexual cells are in abeyance.

The "instability of tissue" mentioned by Mr. Paul might be controverted by (1) limiting the protein intake, (2) keeping the gastro-intestinal organs healthy, and (3) guarding against prolonged local irritation. As regards treatment, advantage might be taken of the knowledge that creatinuria occurs in hyperthyroidism, and that throughout the greater part of the growth period, during pregnancy, and in the puerperium the excretion of creatine is an occurrence so regular that it might be regarded as entirely physiological.—I am, etc.,

Upholland, Lanes, Feb. 28th.

J. THOMSON SHIRLAW.

SIR,—The letter of Mr. Frank T. Paul, in your issue of February 24th, and that of Mr. E. G. Fenton, on March 3rd, raise points in regard to the genesis of cancer of great interest. That tumours are the result of the excessive growth of ordinary tissue cells will be agreed by most pathologists. The problem is to explain the factor which causes this excessive growth. Most of the body tissues are actively growing, but their growth activity is controlled, so that although excessive growth

may occur occasionally, as when a damaged area requires to be repaired, the process is arrested once the damaged area has been restored. In tumours, on the other hand, the excessive growth is continuous, and persists during the life history of the tissue cells concerned, even if they are transplanted into another animal. Clearly a genetic change has taken place in certain cells for excessive growth.

I have attempted to explain how this change takes place, and its nature, in a paper published in this *Journal* on April 30th, 1932, and more recently in a book called *The Origin of Cancer*. The problem resolves itself into two questions. What is the change that has taken place which results in the tumour cell growing at an excessive rate? And secondly, What is it that causes this change? As I have pointed out, I believe we can answer the first question, but the second is more difficult.

There seems to be a very general desire on the part of your correspondents to attribute the cause of the change to factors in the environment, such as diet, manner of living, etc., but there are good reasons for believing that environmental factors have very little to do with the incidence of tumours. The susceptibility of the tissues to undergo the change which results in tumour appears to be an inherited genetic factor. This unstable character of the tissues has been handed down through many generations, and like any other inherited defect tends to increase in an unchecked population.

This view is supported by experimental work on mice, and by the observed fact that when tumours are found in uniovular twins both twins have the same type of tumour in the same situation at approximately the same time, and that no examples have been found of one uniovular twin with a tumour which was not present also in the other twin. As tumours usually occur late in life the twins cannot be subject to the same environment, and the only common factor would appear to be their genetic identity. This view is not likely to be very popular, as it does not open any very obvious path towards the control of tumours, but our object is to arrive, if possible, at the truth, however unpalatable, as it is only by so doing that we can hope to make progress towards the solution of this problem, which far too long has eluded us.—I am, etc.,

London, W.1, March 3rd. J. P. LOCKHART-MUMMERY.

SIR,—Before the days of substitution therapy Richard Cabot pointed out that pernicious anaemia was essentially a disease of the cancer age. Now that it has been demonstrated that pernicious anaemia is a deficiency disease it might not be illogical to consider cancer as a disease of the pernicious anaemia age, and to inquire as to the possibility of the cause of cancer being found in the lack of some essential substance in a susceptible subject.

Most of the so-called cures of individual cancer cases which one has observed have been the result (or apparently so) of mixed treatments by various substances, plus dietary restrictions of various sorts, but chiefly by a reduction of the protein element and an increase in the vitamin-containing vegetables and fruit. The common factor in most of the cases noted has been that of diet. Might not research along these lines, as suggested by Dr. W. Mitchell Stevens in your issue of February 24th (p. 352), lead to something simple in the way of cancer cure, which, as Sir William Willcox (*British Homoeopathic Journal*, xxiii, No. 2, 133) recently said, may have been there, just round the corner, awaiting recognition?—I am, etc.,

London, N.7, March 4th.

W. LEES TEMPLETON.

Ovulation and Menstruation

SIR,—I was very pleased to read Dr. Novak's letter in your issue of March 3rd (p. 401), for my article, written in reply to the paper he published in the *Journal* of September 23rd, 1933, showed that our differences of opinion call for correspondence. Just as Dr. Novak now takes exception to some of my views, so did I disagree with some which he expressed.

We disagree, in the first place, on the use of the word "menstruation." I prefer to restrict the word to periodic uterine bleeding in cycles which are ovular in type, mainly because students have difficulty in discriminating between normal uterine bleeding and pathological haemorrhage, and also because I believe that anovular bleeding in women should be regarded as pathological. My feeling is that there will be great confusion if anovular uterine haemorrhage is regarded as physiological. For example, in Dr. Novak's letter he refers to the post-menopausal haemorrhage caused by granulosa cell tumours as "menstrual" bleeding, a description which few will accept, and which would, if widely used, add further to the existing confusion in the nomenclature. The second point upon which we differ is the frequency of anovular cyclical haemorrhage. If Dr. Novak will refer to his article of September 23rd, I think he will agree that it creates an impression that anovular cyclical bleeding is not infrequent in apparently normal women. I am not prepared to accept this opinion, but regard anovular bleeding as relatively rare and of a pathological nature.

I have always admired the wonderful animal work of Corner, Hartman, Hisaw, and Allen, but I do not agree that the interpretation of the physiology of the human menstrual cycle must necessarily be dominated by the results they have obtained with lower animals. Perhaps I have in mind the fact that menstruation in the human subject was for many years regarded as being homologous with the pre-oestrous bleeding of the bitch—a view which is still retained in some English textbooks of gynaecology. Again, it is not yet established that the female sex hormones, which have such well-marked effect in lower animals, are of comparable importance in the human subject.

I agree absolutely with Dr. Novak in his view that reproductive endocrinology is in an unsettled state, and I also realize how difficult it is to obtain reliable human material from which information can be obtained of the physiology of menstruation. Although I disagree with Dr. Novak's views on the incidence of anovular bleeding in normal women, I have every respect for his own admirable work, nor did I intend that any of his other publications or those of Corner, Hartman, or Hisaw should be included among those criticized in my article.—I am, etc.,

WILFRED SHAW.

London, W.1, March 5th.

SIR,—I wish I could think that Dr. Wilfred Shaw will be wise enough to take Dr. Novak's well-merited rebuke to heart. Judging, however, from his recent papers, I am afraid that Dr. Shaw imagines that he is nearing the summit of Mount Olympus, and, therefore, is beyond approach or reproach. In these circumstances, and as one of the oldest of those who in this country have attempted to solve the problems associated with the reproductive functions, I deem it my duty to endorse every word of Dr. Novak's letter.

With regard to the scientific point at issue, I will content myself by recalling that so long ago as 1910 I stated in the first edition of my *Principles of Gynaecology* (p. 76) that menstruation can occur without ovulation (and ovulation without menstruation); and this, as Dr.

Novak says, is generally accepted to-day by those who interpret properly the word "menstruation" and understand its significance. When I read Dr. Shaw's paper in the *Journal* of January 6th I was seriously disturbed, not only on scientific grounds, but even more because of the contemptuous way in which he referred to the "American school," whose distinguished investigators have done so much to throw light on the reproductive functions; and because he assumed an "oracular position" which, as Dr. Novak justly implies, is quite unwarranted by anything Dr. Shaw has done. I do not know of whom Dr. Shaw's "school" consists. He himself appears to be a disciple of a certain German investigator.

I fear that Dr. Shaw has been spoiled by the absence of criticism—he will find plenty in regard to his views on different subjects in the new (fourth) edition of *The Principles of Gynaecology* (1934), although his name is not mentioned—and he has assumed that everyone has "swallowed wholesale" all that he has written, as, indeed, may be the case in not very well informed quarters. It so happens that Dr. Shaw has been immune from criticism for several reasons: no one has wished to impede or discourage one of the few clinical gynaecologists in London who are attempting to do research work; secondly, most of his communications have been published in journals in which no criticism is possible. I should not like our American colleagues to imagine that in this country Dr. Shaw's views are those of all of us who are interested in the subjects about which he has written. Yet even in regard to his last paper, unfortunate though it was, I should have refrained from public comment had not Dr. Novak shown how deeply Dr. Shaw has wounded the brilliant band of workers in America who have really scientifically and effectively advanced our knowledge. I did, it is true, at the time of publication, express to friends in this country, both verbally and in letters, my disapproval of Dr. Shaw's pontifical attitude.

I would observe once more, as I have often done before, that such subjects as menstruation cannot be usefully studied by histological methods only. All Dr. Shaw's statements come to us by way of the microscope lubricated with "midnight oil," and perhaps of a few clinical reports. He has, I believe, entirely ignored comparative physiology, biochemistry, and experimental methods. Without these, and the power to appreciate work based on them, Dr. Shaw is wasting his time and making himself ludicrous by an assumption of superior knowledge, to which those of us who are less confident of the final truth, but have sought it more scientifically than he, have been exposed.—I am, etc.,

Liverpool, March 3rd.

W. BLAIR-BELL.

Ovulation and the Human Sex Cycle

SIR,—Following upon a leading article on the above topic in the *British Medical Journal* of January 16th, 1932 (p. 108), correspondence appeared in the issues of January 23rd and February 6th of the same year over the names of Dr. Wilfred Shaw and Dr. J. M. Robson, of whom the former adduced evidence in favour of restricting ovulation in the human subject to a narrow margin round the fourteenth day of the cycle, whereas Dr. Robson was of the opinion that the existing evidence did not justify so strict a limitation.

The question as to the time at which ovulation occurs has been approached from different angles, and data relevant thereto have been derived from:

1. Histological studies of the endometrium and of the changes which it undergoes under the influence of corpus luteum hormone after ovulation.

2. Direct observation of the ovary at the various stages of the cycle.
3. Recovery of ova from the tubes.
4. Determination of a cycle in the activity of the uterine muscle, and deduction of ovulation from changes therein dependent upon the inhibitory properties of corpus luteum hormone.
5. The probable age of young embryos.
6. Records of restricted periods of copulation in the human subject and in monkeys.

In a recent review of the literature Robson¹ concludes that, although ovulation most frequently occurs about the middle of the intermenstrual period, a considerable mass of statistical data indicates that ovulation may take place at any time of the cycle. In this view he supports that expressed by Dickinson² after a review of the literature up to 1927, and by Evans and Swezy³ at a later date.

To the evidence which has been accumulated from the various sources specified it may be pertinent to make a contribution. The occurrence of faint bleeding on a single day during the intermenstruum has been reported by many gynaecologists, and is generally considered to be an indication of the ovulatory process. In an isolated case recorded by Simpson and Evans,⁴ its occurrence over a period of twenty months was observed to vary in different cycles between the fifteenth and nineteenth days of the period. Papanicolaou,⁵ who made a study of the correlation between vaginal smears and ovarian cyclic changes in seventeen women, observed erythrocytes as early as the seventh day in some and as late as the seventeenth day in other cases. In fifteen cycles of twenty-four to twenty-six days' duration in a single subject erythrocytes were found at varying dates between the ninth and fourteenth days, the highest frequency of ovulation lying between the twelfth and thirteenth days. As the figures are based on an indirect method and not on direct observations of the ovaries, their value depends largely on the extent to which they are supported by other similar cases. It is for this reason that the following particulars are given of the occurrences of the ovulatory sign (so-called) over a period of two years in one and the same subject, aged 40, in whom the number of cycles was 29, the average length of cycles was 28.25 days, the number of appearances of "ovulatory sign" were sixteen (see below), and the average duration of menstruation was five days.

* Counted from first day of last menstrual period.

It is possible that erythrocytes were present at intermenstrual stages in the cycles which are left blank, but no microscopical examination was made, and the data refer to a manifest sign.

Hartman⁶ has reported finding interval bleeding in 75 per cent. of 105 cycles in monkeys at a favourable time of the year. There is, at present, no conclusive evidence that this phenomenon of slight bleeding is, in reality, an infallible sign of ovulation, but, on the assumption that it is, the data given above would provide evidence (a) that ovulation can occur as late as, and after, the twentieth day, and (b) that there may be more than one ovulation in a cycle. The distribution also suggests that the onset of menstruation is not determined by the ovulatory process. If reliable data could be accumulated from many such cases, it would then be possible to determine the significance and the value of the phenomenon.—I am, etc.,

Edinburgh, March 3rd. ANNIE M. HAIN, M.A., Ph.D.

P.S.—Professor Novak's letter, which we observe in to-day's issue, plays a just tribute to the investigations of the "American school" in this matter.

Basal Narcosis in Anaesthesia

SIR,—Our experience with avertin as the routine method of induction in over 2,000 gynaecological operations has proved it to be a procedure which is of great value and, with some simple safeguards, which is eminently safe. The letters of Sir Francis Shipway and others (*Journal*, March 3rd, p. 400) have directed attention anew to the supreme importance of these safeguards. There would seem to be no doubt that in the past deaths from respiratory failure following the use of avertin have been caused (a) by the employment of an excessively large dose in an ill-advised attempt to produce complete anaesthesia, or (b) by associating with it an unduly large amount of such respiratory depressants as morphine. In our own experience we early found that the reduction of the pre-anaesthetic morphine from 1/4 to 1/8 grain resulted in an immediate lessening of respiratory depression following the administration of avertin (*Lancet*, May 31st, 1930, p. 1177). On these matters Sir Francis Shipway and others had previously issued a warning to the profession.

In view of the current interest in the various classes of pre-operative medication it would seem opportune for us to state that our further experience with avertin has confirmed us in the views previously expressed in this *Journal* (December 5th, 1931), after a study of its use in our first 1,000 cases. We have convinced ourselves:

1. That in a dosage of 0.08 to 0.1 gram per kilo of body weight avertin is a safe drug. *In 2,000 cases there has been no mortality or morbidity traceable to its use. The total mortality from all causes was ten.*

2. That it possesses outstanding advantages in the ease, comfort, and certainty of its induction.

3. That it largely eliminates post-operative complications, such as sickness, bronchitis, and bronchopneumonia. In these respects it has created a virtual revolution in the conditions obtaining in our wards from the standpoint both of the patients and of the nursing and medical staffs.—We are, etc.,

Royal Infirmary, Edinburgh,
March 3rd.

JAMES YOUNG.
N. STUART FRASER.

Carbon Dioxide in Barbiturate Poisoning

SIR,—Mr. R. J. McNeill Love, in your issue of February 24th, makes some shrewd comments on the danger of basal narcosis, and offers valuable hints as to the procedure in cases of poisoning. He has, however, completely omitted from his article all mention of carbon dioxide—to my mind the most valuable agent of all, especially in cases of respiratory depression with avertin. I have never had a case of respiratory failure and cardiac embarrassment with this narcotic that failed at once to respond to the administration of carbon dioxide, with or without oxygen.

It would seem, too, that carbon dioxide hastens the return to consciousness in these cases. This seems difficult to explain, since avertin is almost entirely excreted in the urine. Possibly the raised blood pressure causes more blood to flow through the kidneys and better elimination, and certainly the increased ventilation of the lungs will get rid of any ether vapour from the alveolar air, if this has been used in addition to the avertin.

In my opinion, during operations such as thyroidectomy, where one is faced with the probability of a severely damaged myocardium, the indiscriminate use of cardiac stimulants is rather like flogging a tired horse.—I am, etc.,

Guildford, March 2nd.

A. BARNESLEY.

Sudden Circulatory Failure and Diabetic Coma

SIR,—I read with interest the letter of Drs. Fuller and Himsforth (March 3rd, p. 405), and also that of Dr. Douthwaite (February 24th, p. 353). As the latter says, there is much to support the conclusions arrived at by Dodds and Robertson in their article on the cause of death in diabetes (*Lancet*, 1930, i, 852).

Two additional factors which support their view that death results from circulatory failure are:

First, that in many severe diabetics there is electrocardiographic evidence of myocardial change, as shown by considerable flattening of the T wave in all leads. The supposition that the imperfect metabolism of the diabetic leads to malnutrition of the myocardium is, I think, reasonable; but in cases in which I have found this change to be present it is of interest to note that the appearance of the curve has remained unaltered after treatment which has controlled the diabetes.

Secondly, in older patients at any rate, the common association of diabetes and the big-vessel type of vascular sclerosis (affecting the coronaries) must be borne in mind.—I am, etc.,

JOHN R. H. TOWERS.

Leeds, March 2nd.

Dermatitis Due to Sodium Evipan

SIR,—In your issue of February 24th there were three most interesting articles on basal narcotics. Dr. H. W. Featherstone, at the end of his paper, included some remarks on these drugs from the anaesthetist's point of view, but did not mention that some of them occasionally cause a severe dermatitis on the hands of those employing them, totally different to those transient erythemas sometimes seen affecting patients after their use. In 1932, in the *Journal of the American Medical Association*, Kulchar reported a case of contact dermatitis due to avertin in an anaesthetist, characterized by an erythematous-squamous eruption aggravated by each exposure. Now I wish to report a case due to the use of sodium evipan.

An anaesthetist consulted me concerning a rash on the back of his hands; this had troubled him for almost two

weeks, and was a very discrete, papulo-vesicular eruption, which showed exacerbations several times a week, and which tended to indicate a contact dermatitis. As he had been handling procaine, ephedrine, and sodium evipan, patch tests were performed with these three substances. The tests to procaine and ephedrine were negative, but the evipan patch showed a marked vesicular eruption, which lasted for almost four days. Similar patches applied to controls gave negative results.

It is interesting to note that the patient gave a history of having cut his finger about three weeks before, when filing off the top of an ampoule of sodium evipan.—I am, etc.,

G. A. GRANT PETERKIN.

Skin Department, Edinburgh Royal
Infirmary, Feb. 27th.

Post-vaccinal Encephalitis

SIR,—I note that in your summary of the discussion on vaccination, which took place before the Epidemiological Section of the Royal Society of Medicine on February 23rd (*Journal*, March 3rd, p. 397), I am made to say that post-vaccinal encephalitis was not a rare disease and that about 1,000 cases had been reported from all countries. The second statement represents, of course, only a rough estimate, but it is probably not far from the truth. The first statement, that post-vaccinal encephalitis is not a rare disease, may quite likely have emanated from me while replying to many questions, but what I really intended to convey was that post-vaccinal encephalitis was rare, but not extremely rare, and, further, that its importance was not to be measured simply by its rarity when determining the choice between voluntary and compulsory vaccination during a period of variola minor.—I am, etc.,

Lister Institute, S.W., March 3rd.

J. C. G. LEDINGHAM.

"Fourth Disease" and Glandular Fever

SIR,—With regard to the existence of a "fourth disease" in addition to the common exanthemata—measles, scarlet fever, and German measles—may I point out that glandular fever may be accompanied by an eruption indistinguishable from German measles, and the occipital (and other) glands may be enlarged. In other cases it may produce eruptions resembling measles or scarlet fever, or eruptions not typical of any of these. A single case may have more than one type of eruption during its course.

As there is reason to believe that glandular fever has again become prevalent during the last few months, it would be advisable to keep it in mind, both in sporadic cases with eruptions and in infectious diseases hospitals.—I am, etc.,

London, W., March 3rd.

H. LETHEBY TIDY.

Inheritance of Mental Deficiency

SIR,—In your issue of February 24th (p. 355) Dr. Ian D. Suttie occupies a good deal of space, in which he succeeds in showing how little he knows about the principles of heredity. Anything more than the crudest elements of modern genetics appears to be beyond him, and of any understanding of the broader principles of biology there is not a trace. This is perhaps not surprising, as Dr. Suttie's activities have evidently been exerted in other directions. His outlook is a rather narrowly psychological and medical one. Yet he considers himself capable of instructing a biologist and geneticist in the interpretation of a particular pedigree.

In pursuance of this narrow point of view he tells us that a hereditary interpretation is "unverifiable in regard

to indefinite characters such as mental illness and defect, particularly when we take into account the smallness of human families and the length of 'generations' and impossibility of experiment." As the sentence quoted contains all the special pleadings which one generally hears from those of Dr. Suttie's outlook, it may be worth while dealing with them, especially as the rest of his letter contains nothing of any value.

I presume that even Dr. Suttie would not deny the fact that innumerable physical defects and abnormalities in man are inherited as perfectly definite and fixed entities from generation to generation. If he is inclined to do so, perhaps he will consult my book, *Heredity in Man*, or any other work he can find on the subject. At any rate, no one of normal mentality who has considered the evidence for the inheritance of physical defects has any doubts on the subject, so far as I am aware. The evidence is too formidable, too extensive, too conclusive, to leave any room for doubt. Now these facts of inheritance as fixed units apply equally to abnormalities which wholly or partly involve the nervous system. Peroneal atrophy is a case in point. In one published pedigree, 101 descendants from a single affected individual included twenty-one who were affected, and the particular method of inheritance was clear from the pedigree. A Swedish pedigree of myoclonic epilepsy, including over 2,000 individuals in seven generations of descent, shows that this rare condition is inherited, but by different rules from the last. Both these conditions involve the muscular system as well as the nervous system, but the effect on both systems is equally specific. Huntington's chorea is another nervous condition, ending in dementia, the inheritance of which cannot be disputed by anyone who examines the published pedigrees. In a juvenile form of amaurotic idiocy, recently investigated by Sjögren in Sweden, the progressive neurological and ophthalmoscopic symptoms were strikingly constant, and of the inheritance there is again no doubt. The same author has made an investigation of a marked form of feeble-mindedness, with interrelated pedigrees including some 1,500 persons. The affected individuals showed remarkably uniform symptoms, and although the inheritance is recessive, there can be no question that heredity and not environment is responsible for the condition.

It is therefore clear that anyone who admits the facts of physical inheritance must also admit that many abnormal conditions of the nervous system, and mental defects as well, are inherited. I have not, of course, mentioned a tithe of the evidence for mental inheritance. Some of the recent evidence on the inheritance of mental defect has been summarized and discussed in the *British Journal of Medical Psychology* (vol. xiii, page 254). I would ask Dr. Suttie to do me the honour of reading and digesting that paper, and the original works to which it refers, before he again puts pen to paper under the illusion that the difficulties to which he refers prevent any proof of the inheritance of mental defect.—I am, etc.,

London, W.C.2, March 1st.

R. RUGGLES GATES.

* This correspondence is now closed.—ED., B.M.J.

The Tuberculosis Problem

SIR.—Your correspondent "A. R. F." has disturbed a hornets' nest, and I would fain hope that out of evil good may come. Speaking with some authority on this problem, which I have been studying for more than half a century, and with an intimate knowledge of the difficulties that beset all of us who have tried to shed light upon the darkness that envelops the solution of the greatest problem in medical science, I sadly fear that politicians and bureaucrats have made confusion worse confounded.

The correspondence so far shows the muddle of the bureaucratic experts. One writer, Dr. J. D. Macfie, tells us there are "far too few beds in most counties and cities," and another, "E. N. R.," tells us that "during the past few months we have been unable to keep our sanatorium beds filled owing to the lack of new cases of tuberculosis." The problem of the prevention and treatment of this widespread scourge must be attacked anew with new methods and new weapons, and (as "A. R. F." suggests) the medical profession as a whole should rise to put an end "to such a parody of scientific organization against this scourge." The solution of this problem needs the co-ordination and education of the whole profession, and since clinical skill and knowledge are essential for the detection, treatment, and even prevention of tuberculosis it was a grave political blunder to place in the hands of medical officers of health—a political bureaucracy—duties and responsibilities which must be borne mainly by the medical practitioners, who are the first to make contact with this disease and should be the first to deal with the victims in the home before tubercle bacilli have appeared in the phlegm, and thus the disease has become a danger to the family and to society. In the daily round physicians, surgeons, and general practitioners alike have to deal with tuberculosis, and should be able to recognize the disease and apply scientific methods of diagnosis and treatment to the commonest form of tuberculosis—best called phthisis—which is the essential source of infection long before—maybe many years before—the disease has actually become infectious. Thereby we shall find the secret of success which has so far eluded us.

In 1909 I began my tuberculosis campaign in London, and in 1913 I had established thirteen tuberculin dispensaries (clinics) in various centres in Great Britain, chiefly in London, thus inaugurating a plan of attack by means of early diagnosis and prompt treatment on the scientific lines suggested by Robert Koch in 1891. I think I can prove by concrete evidence, and figures that we must return to some such system of attack with the weapons of science, if we wish to succeed on a large scale. Medical opinion is already showing a trend in this direction, and the L.C.C. results seem to prove clearly that the bureaucratic system has been a ghastly failure. It is time that public opinion should not only know but realize that the annual expenditure of more than £3,000,000 on this Government system has hardly touched the fringe of the problem.

Now is the time for the medical profession to "take arms against a sea of troubles" caused by this widespread and cruel disease. Let us realize the fact of failure in the past and make a patriotic effort to help the helpless, distracted, and poverty-stricken multitude to obtain satisfactory treatment for their otherwise unrelenting disease before it is too late—before the disease has sapped their health and strength and destroyed their industrial capacity and efficiency. Mere discussion in the *British Medical Journal* cannot help the victims. I would ask "A. R. F." and other correspondents to visit the only tuberculin clinic in London, and see for themselves how such an organization might help them and many other medical men to deal with the disease at once and on the spot, before it has become notifiable, by means of scientific rather than haphazard methods. Later we might organize a crusade and win support by holding meetings in London with the object of establishing other clinics for dealing with this disease by the methods of science on a well-organized plan, in which physicians, surgeons, and general practitioners trained in new methods could and would play a dominant part in combating tuberculosis in all its forms and stages among the poorer members of society.—I am, etc.,

London, W.1, Feb. 21st.

W. CAMAC WILKINSON.

SIR,—In view of the interest which is at present being taken in the diagnosis of pulmonary tuberculosis and the at present apparently impossible task of obtaining medical men who will and can diagnose this condition, at a stage when it can be cured, I am somewhat reluctantly making the following remarks.

It is now generally admitted that a physical examination of the patient will not carry us very far, and I, among others, have suggested the abolition of the stethoscope as a means of more early diagnosis. It will, I think, be sufficiently obvious that examining the sputum for tubercle bacilli, if relied on for early diagnosis, will usually end in fatal delay. Having got rid of two methods which have in the past been regarded as essentials, I now come to another method which is at present thought to be of great help in these cases. I refer to x-ray examination, and for the diagnosing of early cases I think this method is also of very little practical value. If we remember that the x-ray film only shows shadows, and these must be very considerable in order to be visible, we must not be surprised at this. What, then, is left for us to do? I would suggest that a careful history of the patient's previous illnesses and a careful study of his symptoms would carry us a long way.

With regard to tuberculosis officers I would suggest that they should frequently visit the sanatorium to which their cases are sent and try to find out, in these, usually obvious, cases where they have gone astray, and learn, by an intensive study of them, how others can be prevented from joining the dolorous company. In conclusion, I would observe that if early cases are to be treated efficiently a sanatorium suitably constructed must be provided.—I am, etc.,

Ayrshire Sanatorium, New
Cumnock, Feb. 27th.

EDWARD E. PREST.

A Falling Birth Rate

SIR,—I find it difficult to regard the falling birth rate with anything else than equanimity. Those in whom it inspires such dark forebodings seem to me to be moved almost entirely by sentiments of political expediency. They appear to be afraid that the proud position this country has won in the past by the not wholly admirable qualities of pugnacity, business acumen, and acquisitiveness may not be maintained by a dwindling population. Those like myself who hold that the most desirable qualities are not the exclusive possession of the dominant races, and who have felt more of the painful duties than the pleasant privileges of nationality, are not likely to share their views.

My blood remains quite uncurdled by Sir James Barr and his school, who for want of selective breeding apparently envisage a world of the future peopled by paupers, moral degenerates, and criminal lunatics. I cannot imagine why he assumes that the seventeenth century had a "small but intellectual population." Surely every age since the dawn of history has had its weaklings, its wastrels, and its simpletons; and I don't see that we have any more than our fair share now. It seems to me that Nature never did weed out the unfit. They have always managed to survive and propagate their species, and their lineal descendants are not the denizens of the asylum, the gaol, and the workhouse, as we should like to think, but our noble and intellectual selves. The waxing and waning of stocks is a matter of common observation. The countryside is strewn with the wrecks of noble families. Village clods with Norman names elbow us in the market-place, and the family trees of some of the brightest names of the present day have their roots in Bedlam.

I fancy possessive instincts unconsciously cloud the scientific outlook of those who are most severe on our

poor relations. They feel that for themselves and their likes the world should be a garden in which no weeds must grow. With little show of meekness they feel that *they* should inherit the earth, and all who do not attain their level are vermin fit only for extermination. I should like to plead for a wider charity. Not only of our superior selves, but of every living thing is the earth the rightful heritage. Only an immediate threat to our existence, not merely a distant fear for the future, can justify our stealing their birthright. The rat in my pantry I may kill. The lion in the desert I should leave alone. I cannot see that the human family is more dangerously threatened by its poor relations now than it has ever been. To meet the problem of the criminal, the lunatic, and the shiftless with demands for their extermination seems to me rather like greeting a hungry beggar with a shot-gun.

If the argument is to be carried to its logical end, why should not practical eugenics be applied to the enfeebled creatures who cumber our hospitals with their gall-stones, gangrenous appendices, and perforated gastric ulcers? Why should a sickly sentimentality offer them the relief of surgery when it is obvious their tainted stock would be better extinguished? Why not let Nature pursue her proper destiny and weed them out? For all we know they may be the bearers of recessive genes for their several ailments. It must be a very misguided benevolence to preserve them to propagate their antisocial taints. And as for those degraded wretches suffering from tuberculosis, notorious transmitters of their polluted strain, squandering the wealth of the world in hospitals and sanatoria, how much more economical and prudent to knock them on the head and spare ourselves an intolerable burden in the future!

I cannot help thinking that man must be more than the product of his genes, and that Nature, so far from weeding out the unfit, always meant some to have ten talents and some only one, with the tendency always towards enrichment. Cannot the same power that made a man from an ape breed a Shakespeare from a sot? If it were a matter of the body alone, man might hope to master his future. But the qualities we call fitness and unfitness are not wholly of the flesh, and to seek perfection along the path of selective breeding is only to bark our shins in the dark searching for what is not there.

There once was a man who determined to make the most beautiful music in the world—but he spent his life buying better and better pianos.—I am, etc.,

Upwell, Feb. 24th

A. J. HAWES.

Medical Examination at the Police Station

SIR,—Regarding certain statements reported in the Press as having been made by Mr. Justice Rigby Swift in two recent cases, I have been expecting to see, in the medical journals, a deluge of letters of protest. For some reason this is not the case, and it appears to me that one particular remark—if correctly reported—needs comment and a protest of the strongest kind on the part of the medical profession. I refer to the case where, in a charge of "being under the influence of drink while in charge of a motor vehicle," a doctor, who had been called by the accused man on his own behalf to examine him and received a fee of 10s. 6d. for so doing, gave evidence adverse to the accused and was rebuked by the judge for accepting a fee in the circumstances as not being "quite nice."

The suggestion here is that a medical man is only entitled to his fee if he is willing to give evidence satisfactory to the accused, instead of doing that which is one of the recognized duties of any reputable man—medical

or otherwise—namely, speaking the truth, the whole truth, and nothing but the truth. I consider that such a remark from a judge is unwarranted, and official attention ought to be called to it. Of the right of a medical man to be paid for his services to a patient there surely can be no question. Whether the patient likes the doctor's opinion has nothing to do with it. One might as well say that a patient who visits a consultant, and after examination is told that he is suffering from a grave and incurable disease, should not pay the consultant's fee, but should only do so if the professional verdict is a favourable one. Such a position cannot logically be accepted.

An idea of this kind is especially to be deprecated when given utterance to by one who, from his great experience and high public position, might be supposed to understand the ethical code of a sister profession. Our sympathy should go out to the medical man concerned, whose attitude was absolutely correct and who was fully entitled to his fee—though for some reason he is said to have refunded it.—I am, etc.,

London, W.1, March 5th.

PERCY B. SPURGIN.

Colonic Irrigation

SIR,—Dr. M. B. Ray, in your issue of February 10th, asks what amount of training is required of those persons who are to carry out colonic irrigation. He asks if they are to be State-registered nurses, members of the Chartered Society of Massage and Medical Gymnastics, or bath assistants. The Education Committee of the College of Nursing feels very strongly that treatment of such a nature demands the services of the trained nurse, working under the direction of a doctor. It would view with grave concern any suggestion that colonic lavage should be carried out by those who had not a full nurse's training, and had therefore little knowledge of the dangers they might encounter in administering the treatment. Mr. Elmslie, in his reply to Dr. Ray in your issue of February 24th, says that "it is really a question of the convenience of organization and of the patient." In the eyes of the nursing profession it is a question rather of the welfare of the patient than his or her mere convenience, and any question of organization must be a secondary consideration. Surely no medical man will lose sight of this point of view when deciding by whom the specialized treatment of colonic irrigation should be given.—I am, etc.,

EMILY E. P. MACMANUS,

Chairman of the Education Committee,
College of Nursing.

London, W.1, Feb. 27th.

Legal Ownership of X-Ray Films

SIR,—The article under this heading in your columns on January 13th is very interesting, but the author does not seem to have borne in mind that x-ray films are taken not only as a matter of diagnosis and treatment, but often with at any rate one other motive. It is difficult to conceive of two or more medical practitioners, be they general practitioner or specialist, arguing between themselves as to who should retain ownership of x-ray films of a case that they as a team may have been treating, so we will look at this matter from the point of view of a general practitioner.

A case of suspected bone or joint injury comes before him. How is he to deal with it? Presumably he will examine it clinically and render any treatment, such as correction of malposition or applying splints, etc., that he may consider necessary. By this time he may or may not feel sure that all is well. In either case, if he is wise, his next move will be the same: he will arrange to have an x-ray picture taken, either by himself or by a radio-

logist. And here the vital question arises. He will not only want the x-ray photograph to confirm his previous actions, and possibly to guide him in his future conduct of the case, but still more will he want it if an action for negligence or malpraxis is brought against him in connexion with the case. I remember at an early stage in my forensic medicine course the lecturer impressing upon his audience the utmost importance of obtaining x-ray pictures of cases of bone or joint injuries attended by them: furthermore, all medical defence associations reiterate this point in their circulars and annual reports. Surely, then, for this reason the general practitioner, even if he is not legally entitled to claim ownership of the x-ray films, would be wise to reach an agreement on the point beforehand, when arranging for the films to be taken.

Under the subheading "Other Suggested Owners" it is stated, "It is fairly certain in law . . . he [the G.P.] is not one of the parties to the contract." This reasoning is difficult to follow, for surely in this connexion there are two separate contracts—namely, (1) as to fee between patient and radiologist, and (2) between the general practitioner and radiologist as to the nature of the x-ray photograph to be taken. If this view is incorrect then it does not seem to matter much how or what the radiologist photographs, and the patient would have no redress if the x-ray examination was done unsatisfactorily.

Surely the general practitioner's answer to the lawyer's question, "What valuable consideration have you given for it?" is that he has used his experience and superior knowledge to direct the patient to a reliable and competent radiologist with precise instructions as to the nature of the x-ray photograph to be taken. In this light the situation is reversed, the radiologist being the agent of the general practitioner and clearly instructed by him as to the duty to be performed. The view that it is difficult to see how the general practitioner can claim of his own right to see the film appears to me to stretch the argument to absurdity. I should imagine that, from the point of view of custom only, most if not all patients would be very disappointed with a doctor who arranged for them to be x-rayed and did not see the film, and would regard him as showing an utter lack of interest in their case; nor can I suppose that any other parties to the x-ray examination would desire otherwise than that the general practitioner concerned should see the films. So much, if general custom is of any validity in law.—I am, etc.,

Medical Contributions to Lay Journals

SIR,—An article with the dramatic title "Motherhood is Safer—if You are Poor," was published in the *Scottish Daily Express* of February 21st. It calls for some comment. Dealing with maternal mortality, "A Famous Gynaecologist" states:

"The first most important cause is puerperal sepsis or infection. By that is meant the introducing of bacteria into the mother during or shortly after the birth of her child, and the giving rise to localized or general disease. The tragedy is that the medical attendant may carry the germ on his hands or clothes; or that, as has been shown comparatively recently, the germ may be present in the attendant's throat without causing any personal inconvenience. Without any symptoms to reveal its presence, a doctor may be his patient's most deadly menace. All women, at such a time, are vulnerable to infection, but Nature renders assistance in the fight."

Such a statement appearing in the lay press serves no useful purpose to the public, and might only bring a highly conscientious colleague, the victim of circumstance, into professional disrepute. The "Famous Gynaecologist"—I am certain he or she is not an obstetrician—by telling only half of the truth, and indeed the lesser half,

indicates that sensational effect has been his main object ; or, to be more charitable, he may be a young writer of limited experience, with little penchant for reflection and *savoir-faire*. The contributor has been content to pillory the medical attendant. He has failed to mention the well-recognized possibilities of intrinsic and auto-infection. (See article in *Edin. Med. Journ.*, 1932, xxxix, No. 2, by the present writer.)

From the lay reader's point of view, also, the article in question is undesirable and harmful. Where is the encouragement for the expectant and potential mother in a contribution the reading of which would inculcate only a dread and fear of pregnancy and parturition into the mind of any woman? Consider the effect of mental anguish and worry during pregnancy on the subsequent labour and puerperium, and their total effects on maternal mortality figures. Some five years ago I wrote in a medical newspaper: "Expectant mothers should, if at all nervous, be told that the vast majority of confinements are easy, natural, and safe. They should not be frightened by articles on maternal mortality in the public press, as such are apt to prove a harmful policy." This should, I think, indicate to the "Famous Gynaecologist" the type of message of hope, comfort, and encouragement which does so much to fortify the expectant mother and render her pregnancy and parturition less morbid.

In conclusion, I would express my extreme disappointment at the increasing number of tactless professional contributions to the lay press by colleagues, and would suggest that "the code" be readjusted to obviate the menace—for so it is. I would appreciate the opinions of other colleagues.—I am, etc.,

Ballachulish, Feb. 27th.

LACHLAN GRANT.

"Cheap Anaesthesia"

SIR,—Dr. Graeme Bentlif may congratulate himself on the fact that he lives in the sunny South instead of the frozen North. If he had his wages calculated by Scotsmen, and they were paid by the same people who calculated them, he would realize what value is put on an anaesthetist's services. There have been articles on fee-splitting in the *Journal* recently ; but the payment of anaesthetists is not a splitting of fees, it is getting a tiny chip off—which is a difficult matter.

A great deal of the trouble is due to the farming-out of the anaesthetic work. It is the same in all trades in this district. A few years ago the colliers had what they called the "butty" system, whereby one or two men in a stall got about £20 a week and the remaining eighteen—who did all the work—got practically starvation wages. This has been put an end to, and each man gets his money according to the tonnage he gets out. So long as the account for the anaesthetist's work is sent to the patient by the surgeon there will be dissatisfaction. I have met many patients who thought that I got half the surgeon's fee for giving the anaesthetic! The result of this low-fee farming-out business is that in the whole of Yorkshire, I believe, there is only one man who attempts to make a living as an anaesthetist. The others are just in general practice and give anaesthetics as a side-line because they find it impossible to live on the fees which they would obtain as anaesthetists. This has retarded the advance of anaesthetics, because, on the fees obtained, anaesthetists cannot be expected to afford either to travel and really see what is happening in other places, or to pay for expensive apparatus which, though it may give safer anaesthesia for the patients, is not a business proposition to buy and maintain.

Little attention is paid to anaesthetics in the curriculum. We recently had at one of the hospitals to which I am attached a house-surgeon appointed who had given six anaesthetics only before he came on duty and was liable

to be called upon to give anaesthetics in the most grave emergency cases. The public will never get the best anaesthetic service until they pay the anaesthetist direct, and pay a proper fee.—I am, etc.,

Doncaster, Feb. 21st.

E. J. CHAMBERS.

Lung Disease after "Gassing"

SIR,—May I be permitted to thank Dr. G. Basil Price for drawing attention to a misquotation and an error in my recent article on gas sequelae (*British Medical Journal*, November 11th, 1933). As he surmises, the decimal point was misplaced in my original manuscript. I regret that I am unable to give the source of the quotation with any certainty. I believe that it came from the Continental literature, which is hard to come by in New Zealand, and I have not got the original article by me.

The War Pensions Appeal Board in Auckland has not made a special study of the incidence of pulmonary tuberculosis following chest injuries. We have records of twenty-two cases in which it was reasonable to believe that the parietal pleura had been penetrated. In eight cases tuberculosis had supervened, and in two others it could not be excluded with certainty at the time of examination. No inference as to the incidence of tuberculosis can be drawn from these figures, as the Board has no access to the files of men with penetrating chest wounds as a whole. Dr. Price's article in *Tubercle* of December, 1929, had escaped my notice, and I wish to express my gratitude to him for drawing my attention to it.—I am, etc.,

Auckland, New Zealand, Jan. 15th.

W. N. ABBOTT.

Pruritus Ani

SIR,—The interesting letters on this subject cover most of the ground. My experience is that the majority of the cases are due to a fold of mucous membrane acting as a wick and allowing the succus entericus to keep the skin in this region moist. The second most common cause is *Enterobius vermicularis*, whilst a not uncommon cause is dietetic. In connexion with the latter cause I have recently had an interesting case of a woman, aged 62, complaining of constant pruritus ani. She was thoroughly examined, but no cause for the pruritus could be found. X-ray treatment "cured" for two months. Ultimately the patient found out that by refraining from eating apples she was free from irritation. Everyone appreciates the fact that alcohol and such beverages as coffee, etc., often cause this form of "idiopathic" irritation, but this was the only case I have seen of apples being incriminated.—I am, etc.,

Bath, Feb. 27th.

The Services

HONORARY PHYSICIAN TO THE KING

Air Commodore A. W. Iredell has been appointed Honorary Physician to His Majesty the King, vice Air Commodore H. V. Wells, C.B.E., who has vacated the appointment on retirement from the Royal Air Force.

The King has conferred the Efficiency Decoration of the Territorial Army on Colonel A. R. Moodie, A.D.M.S., 51st (Highland) Division ; Major and Brevet Lieut.-Colonel R. A. Lennie, R.A.M.C.(T.A.), and Majors W. Leslie, M.C., and L. McI. Weeks, M.C., R.A.M.C.(T.A.).

The War Office announces the promotion of Major-General J. A. Hartigan, C.B., C.M.G., D.S.O., M.B., the new Director-General, Army Medical Services, to Lieutenant-General.

Obituary

PROFESSOR F. C. PURSER, M.D.

President of the Royal College of Physicians, Ireland

It was with deep regret the medical profession in Ireland heard of the unexpected and sudden death of Professor Francis Carmichael Purser, which occurred at his residence, 32, Fitzwilliam Place, Dublin, on February 28th.

Dr. Purser was born in India, the son of a high official in the I.C.S., and received his early education in the Grammar School, Galway. He entered Dublin University, where he had a distinguished career in arts, and subsequently in medicine, and received his medical degrees in 1899, graduating M.D. Dublin in 1901. Amongst his earliest appointments was that of physician to the Richmond, Whitworth, and Hardwicke Hospitals, a post which he held until his death. He was elected a Fellow of the Royal College of Physicians, Ireland, in 1904, and was also a Fellow of the Royal Academy of Medicine, and an ex-president of the Dublin University Biological Association. On the expiration this year of the term of office of Dr.

T. G. Moorhead as president of the Royal College of Physicians, Dr. Purser was elected as his successor. He was a member of the British Medical Association, and a past-president of the Irish Medical Association. In 1933 Dr. Purser was appointed King's professor of medicine at Dublin University, and was also honorary professor of neurology. Dr. Purser belonged to a very distinguished Irish family. He was a nephew of the late Professor John Mallet Purser.

medical school, Trinity College, Dublin, and the late Dr. Louis C. Purser, who was senior Fellow and vice-Provost, Trinity College, Dublin. Miss Sarah Purser, the Irish artist, was his aunt. Dr. Purser is survived by his wife, who is a daughter of the late Dean O'Brien of Limerick, and by a son and three daughters. One of the daughters is a member of the medical profession, and his son is an assistant professor of English literature in Glasgow University.

The following are extracts from an appreciation by a medical colleague and intimate friend of Dr. Purser, which has already appeared in the *Irish Times*:

Dr. Purser's death is more than the passing of the official head of one of the branches of the medical profession of this country, of a lucid teacher, of a distinguished physician. It is the disappearance of a great personality. The positions he held were honourable and important, and his professional accomplishments also were great. His teaching was not only sound, but logical, well arranged, convincing. Students knew where they got good teaching, and they crowded to his lectures. He had the gifts of common sense and good judgement. His critical mind separated the seed from the chaff with ease and little loss of time. For many years past he had taken a special interest in diseases of the nervous system, and without abandoning his work as a general physician, he won for himself the position of specialist in neurology. There were few difficult neurological cases in the country in which his aid was not sought. This is perhaps the most complicated and difficult branch of medical practice, but Purser made crooked paths plain, not only to medical students, but to the practitioners who

called him in consultation. His examination of a case was in itself an education. The position he had attained in neurological medicine was unique, and there is no one to fill the vacancy.

It is generally misleading to mention any one quality as the keynote of a man's character, for even the simplest character has many notes. If forced to name the dominant quality in Purser's character, one would probably say "honesty." It was his honesty—given his courage—which made him so indomitable a Rugby player in his youth. It was his honesty which—given his native abilities—made him so thorough and competent a physician. His honesty compelled him, not infrequently, to hold opinions very different from those of his associates, but at the same time it held their respect. To meet him was to realize his essential goodness. His modesty was surprising. He held various important appointments, but he sought none of them. Unwillingly, he became president of the Royal College of Physicians, and only when he was persuaded that his duty demanded of him to accept the burden of the office. He had to be persuaded more recently to accept the chair of medicine in Trinity College. He disliked publicity, and some of the necessary duties of his position were positively distasteful to him.

His friends, however, do not think mainly of the professor and the president. They think of Frank Purser, the companion of the fireside and the countryside, the wise adviser, the never-failing friend, cultured in art and literature, interested in public affairs. Above all, he loved the countryside in Ireland. Few knew the country as well. He was equally at home on the hills of Kerry, on the bogs of Achill, and in the glens of Donegal, and he was equally at home with the fishermen and peasants in Connemara and with his colleagues in learned societies in Dublin. He loved his holidays in the country, and odd days stolen for country walks. Mountains fascinated him, and there was no high mountain in Ireland that he had not climbed time and time again. A few years ago he bought a farmstead in County Wicklow, where he spent most of his leisure, and where he looked forward to spending a quiet old age. He came of a long-lived family, with the gift of retaining their activity to extreme old age, and he had always been of robust physique. His passing was quick and easy. The grief for his friends and for the public is that it occurred twenty years too soon; for he had not yet approached his sixtieth year.

Dr. Purser served in the European War, and was a member of the Order of the British Empire. While a student, and after taking his medical degrees, Dr. Purser was an active supporter of Rugby football. He played in international games for Ireland.

[The photograph reproduced is by Werner and Son, Dublin.]

ALFRED GEORGE BARRS, M.D., F.R.C.P.

Hon. LL.D.

Consulting Physician, Leeds General Infirmary, and late Professor of Clinical Medicine in the University of Leeds

We regret to record the death, on February 28th, of Dr. A. G. Barrs, an outstanding personality for more than half a century in the medical and social life of Leeds.

Born in Leicester in 1853, Alfred George Barrs received his medical training at Guy's Hospital and the University of Edinburgh. In 1875 he graduated M.B.Ed., and in the following year obtained the diploma M.R.C.S. In 1882 he proceeded M.D., became M.R.C.P. in 1884, and F.R.C.P. in 1893. After holding appointments at Guy's Hospital he went to Leeds in 1879, built up a large practice, and attained eminence as a consultant, particularly in cardiac disorders. A paper by him on the use of digitalis in aortic valve disease was published in the

British Medical Journal in 1892, and five years later, in these columns again, he inveighed against the excessive restriction of diet in enteric fever. He was for some time honorary physician to the Leeds Public Dispensary. In 1884 he was appointed assistant physician to the Leeds General Infirmary, and physician about eight years later. For twenty years he served it in this capacity, and was then elected a member of the consultant staff. After holding a demonstratorship in physiology, Dr. Barrs succeeded to the chair of medicine in the University of Leeds, then the Yorkshire College, in 1899, and held that appointment until 1910, when he became professor of clinical medicine. When the University obtained its charter in 1904 he was its first representative on the General Medical Council. In 1921 he was elected emeritus professor of medicine, and his services to medicine generally and to the University were recognized in 1931 by the conferment upon him of the LL.D. *honoris causa*, the occasion being the centenary celebrations of the Leeds medical school. He was a member of the council of, and examiner for, the Royal College of Physicians of London. In 1880 he joined the British Medical Association, was secretary of the Section of Medicine when the Association met at Leeds in 1889, and was vice-president of the Section of Therapeutics at the Bournemouth meeting in 1891. At the outbreak of war in 1914 he received the commission of lieutenant-colonel, and took charge of the medical division of the 2nd Northern General Hospital at Leeds. Dr. Barrs combined a great gift for friendship with a staunch loyalty to causes in which he believed. His wide and profound knowledge, a stern devotion to essentials, and a caustic humour rendered him a most able teacher and a trusted consultant. Broadminded in outlook, he was conservative as regards new departures, and strongly criticized certain developments of State medicine. For many years he edited *Brailhwaite's Retrospect of Medicine*, and critically examined all new advances in therapeutics, selecting the practical from the visionary with a keen eye for truth and error. Yet each new contribution received his careful consideration, and he delighted in that form of controversy which stripped a subject of false trappings and casuistry. Similarly, in his private and social life generosity was allied with healthy cynicism, and his friendships were many, vigorous, and long-lasting. He was a popular and genial chairman of the Leeds Club. Dr. Barrs had been a widower for many years, and leaves no children.

R. A. V. writes:

With the passing of Dr. Barrs a great figure has disappeared from the University and the General Infirmary at Leeds. As one who had the privilege of acting as one of his clerks and later as his house-physician, and in 1931 the honour of presenting him for the degree of doctor of laws *honoris causa* in the University of Leeds, I have especial reason to revere his memory. Dr. Barrs was a great teacher. He taught us the value of observing the minutest details in the histories we took of our patients and in our descriptions of the physical signs. He could be severe, and often was in his criticism, but his strictures never left a sting behind. Indeed, I think it would be true to say that the more he criticized the more we loved him. He was affectionately known by us all as "Dickie." His one desire was always to do the best for his patients. His sympathy and his solicitude for them never failed. To those in trouble he was an ever-constant friend. Many there are who have reason to be grateful for a kindly generosity which was none the less bountiful because it was practised in secret. His ideals were high, and he had a profound distaste for the passing fancies that sometimes cloud the horizon of medical progress. His outlook was distinguished by a robust common sense, which could strip the false from the true with a few terse

phrases that impressed themselves on his hearers and served as a powerful stimulus to their mental processes. His friendship was valued by all those who were privileged to enjoy it. His sense of humour and his gift of adaptation to the company in which he found himself made him everywhere a welcome visitor. The familiar pipe that was his constant companion in his hours of relaxation at the club or on the links seemed typical of the genial good-fellowship by which he was distinguished. The world is poorer for his passing; it is richer for his memory.

T. H. HAYDON, M.B., B.Ch.

Marlborough

By the death, after a short illness, of Thomas Horatio Haydon on February 24th, at the age of 68, Marlborough and a large part of Wiltshire are deprived of the services of a very able practitioner and an old friend.

Dr. Haydon graduated M.B., B.Ch. Cambridge in 1891, and obtained his M.R.C.S., L.R.C.P.Lond. the same year. He was a student at Cambridge and St. Thomas's, and afterwards held the posts of house-surgeon and obstetric house-physician at St. Thomas's, assistant medical officer to the South-Western Fever Hospital, and clinical assistant to the Evelina Hospital for Sick Children. He settled in Marlborough nearly forty years ago, where he built up a large practice, and his services were much in request both by his patients and by his medical confreres. A first-class general practitioner and a successful surgeon, he took a great interest in the Savernake Hospital, and largely assisted in its development from a cottage hospital to, what it now practically is, a general hospital of eighty beds. He contributed various articles to the medical journals, and took an active interest in the work of the British Medical Association, being chairman of the Swindon Division in 1931 and president of the Wiltshire Branch in 1932; he was also chairman of the Wiltshire Medical Advisory Committee, set up by the B.M.A., where his advice was always sound. He was highly esteemed by all medical men in the county, and his skill and kindly manner endeared him in an unusual degree to all his numerous friends and patients. He took an active interest in local affairs—church, Angling Association, British Legion, and golf and tennis clubs. He was also a member of the Territorial Force, served throughout the war, and then retired with the rank of brevet colonel. He leaves a widow.

H. G. T. writes:

Though engaged in general practice, Haydon's post as honorary surgeon to the Savernake Hospital gave him opportunities of surgery of which he availed himself to the full, and in course of time he thus established a reputation as an operating surgeon throughout the county. He was particularly well known in connexion with diseases of the ear. As regards recreations, he rowed while at Cambridge and represented his college on the river. He was also one of the leading spirits at St. Thomas's in putting a boat on the river in the name of the hospital. But his lifelong passion in the direction of sport was fishing. His summer holidays were, of course, devoted to it, and during the rest of the year he loved now and then to snatch an odd day on the Kennet. A recital of the bald facts of Haydon's life, however, can give no idea of the man's extraordinary charm. Children took to him at once, and he was "Uncle Tom" in an honorary capacity to many from the day of their first introduction, while his small patients at the hospital were devoted to him and he to them. But this mention of the hospital makes it almost necessary to say a few words about that institution which he loved so much.

The Savernake Hospital is a good illustration of the fact that greatness does not depend upon size, for it has only eighty beds. It is beautifully situated, just at the edge of the forest, and the spirit of its management is worthy of its surroundings, for not only does the work done there reach a high degree of efficiency, but the medical staff carry it on as a band of brothers, and the matron is, as it were, a sister in the family. To show that the spirit in which the hospital life is carried on is shared by every grade a little incident may be mentioned. The present writer was going round accompanied by the matron when he noticed a man engaged in painting the ward. He expressed surprise at this, considering that the time was Saturday afternoon. The matron's answer was: "Oh, that's the hall porter: he always comes and does jobs like that in his off hours." That is the community of which Dr. Haydon was an honoured and loved member.

Dr. C. E. S. FLEMING writes:

When a famous Justice said that he would rather be a good judge than a great judge, he was expressing a thought that must have been in the minds of many of those assembled in the Church of St. Peter, in Marlborough, to mourn the loss and honour the memory of the beloved physician Thomas Horatio Haydon.

That great congregation of all classes of people from town and country was drawn there, not by the power and prestige of fame, or wealth, or title, or great estate, but by gratitude and affection. Haydon was a man of justly high repute as a medical practitioner, with an extensive practice throughout a large part of Wiltshire. He had worked there for forty years, and was one of the makers of the fame of Savernake Hospital, one of the oldest of cottage hospitals. What made him great was the good quality of everything about him. Quiet in manner, simple in tastes, kind in action, a man of few words who never put himself forward, his one aim in life seemed to be to do good wherever he was, without thought of himself. He must have realized that to do good he must do well and do thoroughly whatever he did, and he thought well—obviously with care and deliberation—so that in all matters his opinion, when he expressed it, was good. Practically interested in everything that was for the individual or communal well-being of the people among whom he lived, his help was always available, and his advice, because it was sound, disinterested, and kindly, was always sought and respected not only in relation to his patients but in all the problems of life—his profession, hospital or private practice, medical science or politics, church, education, local affairs of all sorts. What a position to hold in the community! Not the dominance of money or social position or political prejudice, but the influence of a very real beneficence was carried into the homes of every class and creed—the power of untold worth. Such was the sway of Haydon, one of the splendid examples that make men proud to belong to his profession. He has received the greatest honour he would have desired—the affectionate memory of all men. He has achieved the greatness of goodness.

Dr. WILLIAM PLAYER KENNEDY of Bath, who died suddenly on February 3rd, was born in 1866. He received his medical education at Trinity College, Dublin, where he graduated M.B., B.Ch., B.A.O. in 1889, and obtained the diploma L.M. of the Rotunda Hospital. He proceeded M.D. two years later. His previous appointments before going to Bath included those of resident medical officer to the City Hospital, Liverpool, and assistant house-surgeon to the West Bromwich District Hospital. He had also been medical director of the Lydney and Aylburton Cottage Hospital. In Bath itself he had built up an extensive practice and linked to himself a large circle of friends. He particularly associated himself with

the work of the Eastern Dispensary, of which he was honorary medical officer, the clinical society, and the Bath and County Club. As a medical referee under the Workmen's Compensation Act he was a well-known figure at the Bath County Court during the last thirty years, and in this sphere of work his wide experience and tact enabled him to contribute successfully to the solution of problems which were often of great intricacy. He became a member of the British Medical Association in 1893, and served as a Representative at the Belfast meeting in 1909.

Universities and Colleges

UNIVERSITY OF OXFORD

Election to Faculty of Medicine Board

An election of two members of the Board of the Faculty of Medicine, vice Dr. C. F. T. East and Dr. C. P. Symonds, who are both eligible for reappointment, will be held on June 1st; the members elected will come into office on the first day of Michaelmas Term, 1934, and will hold office for two years from that day. The General Medical Electorate consists of all Oxford graduates in medicine who are members of Convocation. The Board of the Faculty of Medicine includes four members elected by the General Medical Electorate who must be members of that body, and of whom three at least must be persons engaged in teaching one or more of the clinical subjects of the Faculty. Nominations of duly qualified candidates for election will be received by the Secretary of Faculties at the University Registry, Oxford, up to 10 a.m. on May 11th. Each nomination must be signed by six members of the General Medical Electorate, and no candidate will be eligible whose nomination has not been received before that date.

At a congregation held on March 3rd the following medical degrees were conferred:

M.D.—R. E. Havarril.
M.B.—F. E. Buckland, M. S. Good.

UNIVERSITY OF BIRMINGHAM

A course of five William Withering Memorial Lectures will be given in the large theatre of the Medical Faculty Buildings, Edmund Street, on Wednesdays, April 25th, May 2nd, 9th, 16th, and 23rd, at 4 p.m. The first two lectures will be given by Professor E. D. Adrian, F.R.S., on "The Activity of Nerve Cells," and the last three lectures by Professor J. B. S. Haldane, F.R.S., on "Contributions of Genetics to Medical Science." Members of the medical profession are invited to attend.

The Ingleby Lectures, 1934, on "The Toxaemias of Pregnancy," will be given on Thursdays, April 26th and May 3rd, at 4 p.m., in the medical lecture theatre, by Dame Louise McIlroy. Lecture I will deal with the clinical and biochemical investigation of the toxaemias of pregnancy, and Lecture II with treatment.

A course of post-graduate demonstrations arranged by the university clinical board will be given at the General Hospital, the Queen's Hospital, and the Children's Hospital, Birmingham, on Tuesdays and Fridays, from 3.30 to 5 p.m., commencing on March 20th and terminating on July 20th. The course will be given by members of the medical and surgical staffs of the hospitals and will include demonstrations on cases. The fee is £2 2s.

FACULTY OF MEDICINE

The Faculty of Medicine has arranged for two lectures dealing with the regulations appertaining to national health insurance practice, to be given by Dr. H. Guy Dain, chairman of the Birmingham Panel Committee, in the medical theatre on Thursdays, May 17th and 24th, at 4 p.m. The lectures are primarily intended for senior medical students, but members of the medical profession are also invited to attend.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

Committee on Chronic Rheumatism

At the last meeting of the Comitia of the Royal College of Physicians of London the President nominated the following persons to form the National Committee on Chronic Rheumatic Diseases: F. J. Bach, C. W. Buckley, V. M. Coates, W. S. C. Copeman (honorary secretary), A. G. Timbrell Fisher, R. Fortescue Fox, J. Alison Glover, Mervyn H. Gordon, G. Holmes, Lord Horder, A. A. Moncrieff, G. H. Oriel, E. P. Poulton, Sir Humphry Rolleston (chairman), E. C. Warner, Sir William Willcox.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Demonstrations

The spring course of demonstrations of specimens in the museum opened on March 9th, when Mr. Cecil P. G. Wakeley gave the first of three demonstrations on recent additions to the museum. On March 12th, 19th, and 26th Mr. C. E. Shattock will give demonstrations on specimens illustrating surgical diseases of liver and bile-ducts, diseases of joints, and diseases of the large intestine. The demonstrations will be given in the theatre of the College, Lincoln's Inn Fields, at 5 p.m.; they are open to advanced students and medical practitioners.

SOCIETY OF APOTHECARIES OF LONDON

The following candidates have passed in the subjects indicated:

SURGERY.—P. C. Alexander, A. H. L. Baker, E. C. Dax, B. Dayal, G. F. Metcalf, J. R. Owen, J. H. Playne, H. D. Robinson, J. P. Walsh Conway.

MEDICINE.—B. Anderson, J. L. Freer, A. E. Ginn, H. R. Kasday, D. P. King, G. Wilson.

FORENSIC MEDICINE.—A. H. E. S. El Mahallawy, J. L. Freer, A. E. Ginn, H. G. Howitt, D. P. King, L. A. Lewis, A. G. Manley, J. Mason, P. H. Willcox.

MIDWIFERY.—H. M. El Magidi, A. H. E. S. El Mahallawy, J. L. Freer, B. T. Jones.

The diploma of the Society has been granted to A. H. L. Baker, E. C. Dax, H. R. Kasday, D. P. King, H. M. El Magidi, H. D. Robinson, and G. Wilson.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The House of Commons this week passed Supplementary Estimates and discussed the Air Estimates for 1934-5. It is hoped next week to debate the Navy and the Army Estimates. The Rural Water Supplies Bill and other Bills were down for consideration on March 7th. The constitution and terms of reference of the Royal Commission on Durham University were announced.

Accounts of the income and expenditure during 1933 of the General Medical Council and of the Branch Councils, as also of the Dental Board of the United Kingdom, were presented for the House of Commons on March 2nd.

A Protection of Animals Bill, presented by Sir Robert Gower on March 5th, is concerned with the employment of horses and steers at rodeo displays.

On March 5th a report by the Attorney-General on the Birmingham United Hospitals Bill was laid on the table of the House of Commons, and referred to the committee on the Bill.

The Dyestuffs (Import Regulation) Bill was read a third time in the House of Commons on March 5th, and the Workmen's Compensation Act (1925) Amendment Bill a second time on March 2nd. The Registration of Births, Deaths, and Marriages (Scotland) Amendment Bill was reported to the House from the Scottish Standing Committee, with amendments, on March 6th. On the same day the Indian Pay (Temporary Abatements) Bill was read a second time in the House of Commons.

Temperature for Deep Coal Mining

Mr. TINKER, in the House of Commons on February 21st, drew attention to the temperature and conditions in the Parsonage Colliery, Lancs. The Secretary of Mines had said the depth of this pit was 3,850 feet. Mr. Tinker contended that the depth at the coal face was over 4,000 feet. A Royal Commission on Mines had said 4,000 feet was the limit of practical working. At that depth, without ventilation, the temperature was 115° F. At Parsonage Colliery the best possible was done, but in October, when the pit was not as deep as now, the temperature was 100° or 103° F. There was a brisk current of air, but men were working naked, covered with sweat and dirt. A complaint was made from the mine that lads were working at the face. In Spain, if the temperature exceeded 91°, the men were not allowed to

work more than six hours. In Holland persons under 20 years must not work at all in a temperature exceeding 86°, nor adults more than six hours. In Germany they must not work more than six hours if the temperature exceeded 82°, nor in France if it exceeded 95°. Mr. ERNEST BROWN said the temperature which mattered was wet bulb temperature. There were 679 workers in the Parsonage mine, and the wet bulb temperature on the date Mr. Tinker cited was not 103° but 82°. A special committee under Dr. J. S. Haldane had issued seventeen reports dealing with high temperatures. Report No. 6, by Professor K. Neville Moss, dealt with the effect of high temperatures on the miner. Dr. Haldane, in a letter to Mr. Brown, had said that European miners always stopped work before their temperatures rose to any injurious extent. Dr. Haldane also wrote: "On the whole we do not think that any good object would be served by prescribing a limit of wet bulb temperature for the carrying on of work in the mines." Mr. Brown added that the 4,000 foot level had only been taken as a datum line in estimating coal reserves.

Maternity Benefit and Unemployment Allowance

In the House of Commons on February 26th the Unemployment Bill was considered in committee. On Clause 37 (persons to whom and circumstances in which allowances may be granted) Sir H. BETTERTON moved an amendment providing that the whole of any maternity benefit under the National Health Insurance Acts, 1924 to 1932, exclusive of any increase of such benefit by way of additional benefits and of any second maternity benefit, should be disregarded in determining the need of an applicant under Part II of the Bill. He said that, as the Bill stood now, it might be argued that among the resources of the family the £2 maternity benefit which came in by reason of the Health Insurance Acts should be taken into account. It was clear that the needs of the family increased at the same time, because this sum was earmarked for a specific purpose—namely, to help the woman. Mr. BUCHANAN said the amendment was of no value, because the first £2 was merely a book-keeping transaction from the approved society through the person concerned to the doctor and the nurse. What was important was the second sum, which was given to meet the additional human needs of the mother and child, and he trusted that the second £2 would also be left out of account. Mr. HUDSON said that wherever the Board's officer was shown by a young married couple that they had in fact spent the additional money on their needs, the sum would be regarded as being available for those needs, and though the amount would not be disregarded, the needs would be allowed for. The Assistance Board was prohibited from taking medical need into account. It was to make sure that the Board should say that the £2 was definitely for the woman's medical needs that the amendment was moved. Any needs other than medical needs would be part of the needs of the man which the Board would have to take into consideration. The committee agreed to the amendment.

Poor Law Medical Officers in County Durham

On February 27th Mr. BATEY asked the Minister of Health if he was aware that twenty-four district Poor Law medical officers in the county of Durham were complaining of financial loss, owing to 15,000 unemployed people having had their right to medical benefit stopped. Mr. SHAKESPEARE said that a number of insured persons in the administrative county of Durham had recently lost their title to medical benefit under the health insurance scheme. The Minister of Health had seen reports in the Press that a number of district medical officers in Durham had made representations to the local authority for an increase of remuneration. This was a matter for the local authority, with whom he was getting into touch. The district medical service was available for those who were no longer within the insurance scheme. Mr. BATEY asserted that his figures were taken from the Medical Union. Mr. MAXTON asked if Mr. Shakespeare realized that these medical officials were already overworked before this additional work was put upon their shoulders. No answer was given.

Wrongful Removal to Asylum

In the House of Lords on February 27th the EARL OF KINNOSULL drew attention to the case of a Mrs. Broad, and moved "That in the opinion of this House the removal of persons whose sanity is in question should not be dependent on a telephone message nor carried out in the absence of a responsible person." He recalled the circumstances in which Mrs. Broad, owing to a telephone error in an address, was wrongfully removed from her home to an asylum. He urged that only in urgent cases should the telephone be used. In other cases there should be confirmation in writing. Arrangements should always be made with the relatives, and mental nurses should be employed. Viscount GAGE (Lord in Waiting) said that there was no dispute that a most unfortunate mistake was made, and the Government was quite prepared to accept the words of the motion. They agreed with the facts Lord Kinnosull gave. The relieving officer to whose attention the case was first drawn did not himself proceed to remove, he reported on the telephone to the relieving officer whom the Middlesex County Council had appointed to deal with cases of this sort under the Act of 1891. It was clear that the first relieving officer transferred all responsibility to the second official. One of the objects of the procedure was to enable experienced officers to deal with actual removals of this kind of case. The Government felt that a mistake about an address could not be excused on any ground. As for the future, the whole object of this procedure, which was to enable action to be taken quickly and to prevent mishap to the patient, would be lost if they fettered the responsible official's discretion too much. In the whole experience of the Board of Control this was the only case they could recollect of this particular kind. Their lordships could rest assured that it was very unlikely that it would occur again.

The EARL OF KINNOSULL asked the Minister to urge in the Ministry of Health the very great advantage which would accrue if trained mental nurses were used instead of ordinary male nurses.

The resolution was agreed to.

The Sterilization Report

In the House of Commons, on February 28th, Mr. HUGH MOLSON moved a resolution declaring that the facts in the report of the Departmental Committee on Sterilization indicated a state of affairs calling for action. The resolution requested the Government immediately to consider the unanimous recommendation of the committee in favour of legislation permitting voluntary sterilization in certain cases. Mr. Molson congratulated the Minister of Health on setting up the committee and securing distinguished men and women to serve on it. The committee had presented a unanimous report on a controversial subject, though unanimity among medical persons was not common. The report recommended the legalizing of voluntary sterilization of mental defectives or persons who had suffered from mental disorder; secondly, of those suffering from some grave physical disability which had been proved to be transmissible; and thirdly, of persons where there was evidence that they were likely to transmit mental defect or disorder. Mr. Molson pointed out that all the witnesses before the committee held that heredity was an important factor in bringing about these disorders. Investigation at Rostock in Mecklenburg had shown that 67.6 per cent. of the inmates of an institution had one or two parents mentally defective. At Renton in the U.S.A., out of 1,000 mental defectives only 350 had both parents normal. Research was made for the committee through local authorities in England on a group of 3,733 parents, who had 8,841 children. Of these children 2,001, or 22.5 per cent., died. Of survivors 40.4 per cent. of those between the age of 7 and 13 were subnormal and 45.4 per cent. of those over 13. The child was born with predisposition to mental deficiency, and the sordid, squalid environment of a house kept by a mentally deficient woman or man resulted in a child stunted in life as well as in body. Even if mental deficiency were not hereditary it would still be undesirable for mentally defective persons to have children. On that point the report of the Board of Control for 1928 was almost conclusive. From these mentally defective stocks came a large number

of those who composed the "social problem groups" and the criminal element of the population. A separate question was raised where the mind had developed to a certain point and then had become disordered. Evidence in Bavaria showed that half the offspring of a person suffering from schizophrenia were affected, and liable to transmit the taint to another generation. Sixty per cent. of the children were liable to be affected if one parent suffered from manic-depressive insanity, and probably all if both parents were affected. In manic-depressive insanity a lucid interval occurred in which valid consent could be given to sterilization. In schizophrenia voluntary sterilization could only take place when the patient could be safely released from an institution. The strongest case for sterilization was presented by the carriers, who, in the words of the report, were "persons whose family history gives reasonable grounds for belief that they may transmit mental disorder or defect." In their case there could be no question of the reality of consent. As a safeguard the certificate of two medical practitioners would be needed. Most members knew of people, perfectly normal and perfectly sane, who refrained from marriage because some relative had suffered from insanity. There was also the question of physical infirmities, such as those of deaf mutes and blind persons. He had been told by those who had given their lives to serving such unfortunates that the danger of transmitting the disabilities was great, and that they favoured the legalization of sterilization.

Mr. Molson remarked that Dr. O'Donovan had on the Order Paper an amendment suggesting a further Departmental Committee to investigate the legal position with regard to sterilization. Mr. Molson contended that there was no decided case to show whether voluntary sterilization was legal. Whether members were for or against eugenic sterilization, let them legislate and make the law certain. The operation was now legal, and not uncommon if the purpose was to protect the life of the mother.

Wing Commander JAMES seconded the motion. [The debate was interrupted for consideration of the Manchester Extension Bill.] Wing Commander James, on resuming his speech, said public opinion and leading articles in the Press, lay and medical, favoured the passage of a permissive Bill on voluntary sterilization.

The hour for the rising of the House was then reached and the debate ended without an opportunity for Dr. O'Donovan to move his amendment.

Shop Assistants' Hours

In the House of Lords on March 1st the EARL OF FEYERSHAM moved the second reading of the Shops Bill. He said it was based on unanimous recommendations of the Select Committee on Shop Assistants, 1931. The Bill would cover 400,000 young persons under 18 in the distributive trades. The Government would consider other "unregulated" occupations when circumstances permitted. The Bill proposed that for young persons in shops the normal maximum working week should be forty-eight hours, exclusive of meal intervals. For a period of two years from the passage of the Bill the normal maximum hours would be fifty-two. With a forty-eight-hour week, fifty hours' overtime might be worked in a year, and with a fifty-two-hour week twenty-four hours a year, and eight hours in any one week. Catering trades and garages would be allowed to average the hours worked. Existing restrictions on night employment of young persons would be extended to the distributive trades. With certain exceptions young persons were to have eleven hours' rest in every twenty-four, the period including the hours from 10 p.m. to 6 a.m. The second part of the Bill required the owner or the occupier of every shop to provide suitable and sufficient ventilation, heating, sanitary conveniences, washing facilities, and facilities for meals, having regard to the nature and circumstances of the shop. Provisions relating to sanitary conveniences, ventilation, and heating would be dealt with through the medical officers of health and the trained sanitary inspectors. The EARL OF IDDESLEIGH said the Pharmaceutical Society of Great Britain was anxious about the effects of the Bill upon their trade, which deserved every possible protection the House could give. He suggested that pharmacists should receive the protection given by Clause 6 to those who supplied accessories for aircraft, motor

vehicles, or cycles. The EARL OF FEVERSHAM said those engaged as chemists would have to prove to the Home Office that they were under such pressure that averaging should be applied to them.

The Bill was read a second time.

Durham University Roynl Commission

Personnel and Terms of Reference

Mr. MARTIN asked, on March 6th, what were the composition and terms of reference of the Royal Commission to inquire into the affairs of Durham University and of its constituent colleges. Mr. RAMSAY MACDONALD said that, as already announced, the chairman of the Royal Commission would be Lord Moyne. The other members would be: The Countess Grey, Sir Ross Barker, Major A. G. Church, Professor H. R. Dean, the Rev. F. Holmes Dudden, Dr. T. F. Sibly, and Mr. W. Spens. The terms of reference were: "To inquire into the organization and work of the University and its three constituent colleges and into the relation of the University to these colleges, and to report in what respects the present organization can be improved and what changes, if any, are desirable in the constitutions, functions, and powers of the University and its three constituent colleges."

Death from Aplastic Anaemia at Spondon.—Sir JOHN GILMOUR told Mr. Emrys-Evans, on March 1st, that the Factory Department of the Home Office had found no evidence that the death from aplastic anaemia of a man who had been employed in the celanese factory at Spondon, Derbyshire, was attributable to his employment. He was engaged on a different process to the employees of the same factory who died last year.

Conditions in the Hop-fields.—Replying to Mr. Alan Todd, on March 1st, Sir HILTON YOUNG said he had received from the Staffordshire County Council information enabling him to identify farms in Herefordshire and Worcestershire complained of in the recent report of the South Staffordshire County Council Educational Committee on hop-picking. He had sent this information to the Herefordshire and Worcestershire County Councils with the request that they would transmit it to the local authorities of the districts concerned, so that the matter might be investigated and steps taken to remedy any defects.

Disablement Compensation to Miners.—Replying, on March 1st, to Mr. David Davies, Mr. ERNEST BROWN said statistics of workmen's compensation published by the Home Office showed that the numbers of cases of disablement among miners in which payment of compensation started during 1932 included: nystagmus, 1,962; beat-hand, 1,266; beat-knee, 3,076; and dermatitis, 30. These figures did not include cases continued from previous years. During the same year the number of persons engaged in the coal-mining industry who were certified by the medical board to be wholly or partially disabled from silicosis, or from silicosis accompanied by tuberculosis, was 122.

Housing.—Sir HILTON YOUNG told Captain Heilgers, on March 1st, that the numbers of houses reconditioned in England and Wales under the Housing (Rural Workers) Acts, 1926 and 1931, were 869 in the year 1933 and 1,120 in the year 1932. Buildings undertaken without permission while a planning scheme is under consideration, Sir Hilton Young announced on March 1st, are liable to be removed, pulled down, or altered without compensation. Sir GODFREY COLLINS told Mr. Kirkwood, on March 1st, that at May 31st, 1933, the number of State-aided houses under construction in Scotland was 23,505, and at January 31st, 1934, 18,694. In comparing the months of May and January regard had to be paid to the difference in the climatic conditions. There had not been a reduction in the output of houses. The number of State-aided houses completed in Scotland during 1933 was 20,915, which was the highest number erected in any year since 1919, and for January, 1934, the number completed was 1,195, compared with 860 in January, 1933. In an answer, on March 5th, to Mr. John Wilmot, Mr. SHAKESPEARE said that 1,500 Fulham families had been provided

with housing accommodation by the London County Council. In addition, 400 new dwellings had been provided by the borough council. Overcrowding in Fulham remained a problem, and was receiving the attention of the Government. In the meantime, the L.C.C., in common with other housing authorities, were concentrating on the more immediate task of slum clearance.

Vaccination.—In reply to Mr. Summersby, on March 1st, Sir HILTON YOUNG said the number of deaths during the ten years 1923 to 1932 registered as being due to vaccinia, or associated with vaccination, was 118. He could not undertake to introduce legislation during the present session to make vaccination no longer compulsory to the extent it was. Registrars of births and deaths received their instructions from the Registrar-General, and those instructions did not authorize or require registrars to distribute any form other than Form A in connexion with the Vaccination Acts.

Medical Benefit in Lanarkshire.—Mr. SKELTON told Mr. Graham, on March 1st, that approximately 4,000 persons in the county of Lanark, including all burghs except Glasgow, had ceased to be entitled to benefits under Subsection (5) of Section 1 of the National Health Insurance and Contributory Pensions Act, 1932.

Pure Milk Supply Campaign.—Dr. ELLIOT told Mr. Guy, on March 1st, that he would endeavour to enlist the support of the medical profession in his campaign for securing a pure milk supply and an expansion of the liquid milk consumption of the country. In reply to Captain Elliston, on March 1st, Dr. Elliot said he could not make any statement concerning the precise allocation of the sum to be devoted to securing a purer milk supply pending the results of consultation between the Departments concerned and the Milk Marketing Boards. He noted, however, Captain Elliston's suggestion that funds should be available for dairy farmers who were willing to install pasteurization plants as advised by medical officers of the public health services. Answering Captain Elliston, on March 5th, Dr. Elliot said no information was available on which to base a firm estimate of the percentage of milch cows in the dairy herds of England and Wales which were infected with tuberculosis. The measures now in force were designed to remove animals in a stage of disease which rendered them dangerous to public health and to other animals, and not primarily for the eradication of disease as such. Mr. SHAKESPEARE, in a reply on March 6th to Captain Elliston, said local authorities already had powers for stopping the supply of milk infected with tuberculosis. A committee of the Economic Advisory Council was considering measures for reducing the incidence of bovine tuberculosis and for improving the milk supply.

Convictions under the Food and Drugs Acts for sale of adulterated milk are not shown separately.

The Water Shortage.—Replying, on March 5th, to Colonel Ropner, Mr. SHAKESPEARE said it would be an unfair burden on local authorities to give any resident whose water supply had failed a right to call on the local authority to supply him. There were few towns where up to the present there had been serious difficulties. Information received from over 300 rural district councils in response to an inquiry sent to each of them showed that in most rural areas supplies were at present sufficient, or special measures had been taken. Sir Hilton Young was looking into cases of difficulty reported to him, and had also impressed on water undertakers the need of watching the purity of supplies. He had indicated measures to be taken, where necessary, against contamination.

Town and Country Planning.—Sir HILTON YOUNG announced, on March 5th, that resolutions to prepare schemes under the Town and Country Planning Act had been passed for areas in the districts of 117 authorities, and covered over 1½ million acres of land. In addition, schemes covering over 10 million acres were being prepared for areas in the districts of 726 authorities. Fourteen new Joint Planning Committees had been formed under the new Act, of which thirteen were executive. The Greater London Regional Planning Committee, which was advisory, had been reconstituted under the new Act. He did not think steps were necessary to expedite action in cases where use had not yet been made of the new Act.

MEDICAL NEWS

MARCH 10, 1934]

Air Ambulance Service in Scotland.—Mr. SKELTON, answering Mr. Kirkwood on March 6th, said the Department of Health for Scotland had arranged with the county council of Argyll that urgent cases nominated by local medical officers—that is, the patient's family doctor—would be conveyed to hospital by aeroplane. The charges for the hire of the aeroplane, so far as not met by patients, were shared by the county council and the Department of Health. These arrangements would apply to any part of the county, island, or mainland where the service can be operated. The possibility of assisting a similar service elsewhere in the Highlands and Islands was being kept in view.

Housing Conditions in Stirlingshire.—Mr. SKELTON informed Mr. Kirkwood that public local inquiry into the housing conditions in Stirlingshire, was held on January 15th and 16th, and a commissioner inspected the houses on January 29th. His report had been submitted, and was under consideration.

Notes in Brief

It does not appear to the Minister of Health that the Haweswater scheme promoted by Manchester Corporation would provide the best method of supplying additional water to the towns and other water authorities of South Lancashire. Very few musk rats are being caught in the infested areas of Salop and West Sussex. Dr. Elliot sees good reason for hoping that the pest is under control.

Medical News

A Chadwick Public Lecture will be given by Dr. Charles S. Myers, F.R.S., on "The Causes and Prevention of Human Accidents," at the Royal Society of Tropical Medicine and Hygiene, 26, Portland Place, W., on Monday, March 12th, at 5.30 p.m. Admission free, without ticket.

Two lectures on "The Prevention of Disease through Diet" will be given by Dr. Clement Nicory for the Food Education Society at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, on Tuesdays, March 20th and 27th, at 5.15 p.m. Admission free.

A post-graduate lecture on cancer, arranged under the joint auspices of the British Empire Cancer Campaign (Yorkshire Council) and the Leeds and West Riding Medico-Chirurgical Society, will be delivered by Dr. A. T. Todd of Bristol at the School of Medicine, Leeds, on Wednesday, March 21st, at 3.30 p.m. The title of the address is "The Medical Treatment of Cancer," and the lecture will be illustrated by lantern slides. The chair will be taken by Professor G. W. Watson, and all medical practitioners are invited to attend.

The Fellowship of Medicine and Post-Graduate Medical Association (1, Wimpole Street, W.) announces that the ninth lecture-demonstration on iron and liver, by Dr. Clark-Kennedy, at 11, Chandos Street, W., will be given on March 13th, at 2.30 p.m. The tenth lecture, on March 20th, will deal with glands. A fortnight's course in orthopaedics will be given at the Royal National Orthopaedic Hospital, from March 12th to 24th, and will occupy the whole of each day. A week-end course in chest diseases will be given at Brompton Hospital on March 24th and 25th, occupying the whole of each day. Other forthcoming courses include infants' diseases at St. Mark's Hospital, April 9th to 14th; rheumatism at the British Red Cross Clinic, on Tuesday and Thursday evenings, April 10th to 26th. Detailed syllabuses of these courses will be issued shortly.

A provincial meeting of the Tuberculosis Association will be held in the Physiology School, Downing Street, Cambridge, from March 22nd to 24th. The subjects for discussion are: allergy in tuberculosis; the value of blood counts in tuberculosis; tuberculous bacillaemia; the uses of tuberculous institutions; the value of lateral radiography in the diagnosis and treatment of the various

types of the lung and pleura; and the normal chest radiologically considered. The president's reception will be held in Emmanuel College, and the annual dinner and annual meeting in Sidney Sussex College. Excursions have been arranged to the Fitzwilliam Museum, the Pepys Library, and the new Physical Laboratory.

The Royal Sanitary Institute has arranged a sessional meeting at the White Rock Pavilion, Hastings, on Friday, March 23rd, at 5 p.m., when a discussion on "Certain Problems of the Housing Situation, both Present and Future," will be opened by Dr. G. R. Bruce, medical officer of health, Hastings.

We are asked to state that hospitals situated within eleven miles of St. Paul's desiring to participate in the grants made by King Edward's Hospital Fund for London for the year 1934 must make application before March 31st to the honorary secretaries of the Fund at 10, Old Jewry, E.C.2 (G.P.O. Box 465A). Applications will also be considered from convalescent homes which are situated within the above area, or which, being situated outside, take a large proportion of patients from London.

Colonel R. J. Blackham, M.D., has been elected deputy governor of the Honourable the Irish Society. The society was created by Royal Charter of James I in 1613 for the Plantation of Ulster, and owns a great deal of property in Londonderry and Coleraine, besides the salmon fishing on the Rivers Foyle and Bann. It is constituted like the great City Companies, but the Court of Assistants is appointed from the members of the Courts of Aldermen and Common Council of the Corporation of London.

A tour through Austria, Switzerland, France, and Italy begins on March 20th at Vienna, where visits will be paid to the various health resorts and places of historic interest in the vicinity. Proceeding through Zürich to Paris, the Pasteur Institute and Madame Curie's Radium Institute will be visited. The remainder of the journey continues through Nice and Monte Carlo to Mentone for an inspection of Professor Voronoff's establishment, and thence back to Vienna via Venice, Florence, and Rome. Further details may be obtained from Dr. F. Barach, Studien- und Gesellschaftsreisen, Biberstrasse 11, Vienna, 1.

The first Sardinian medical congress will be held at Cagliari next May, when the subjects for discussion will be the haemorrhagic diathesis, malaria and pregnancy, the thyroid gland and goitre in Sardinia, echinococcus disease, and cutaneous leishmaniasis. Further information can be obtained from the president of the executive committee, Professor Luigi Castaldi, Istituto di Anatomia, Cagliari.

We have received the second number of volume I of *Folia Medicinæ Internae Orientalis*, published in Jerusalem. This issue contains articles (with summaries in French, English, and German) on malaria as an epidemiological problem, the diagnosis of undulant fever, indianaemia in acute nephritis, and infectious diseases in Palestine. There are also case reports, society transactions, and a special balneological article on the waters of Calthea.

Lieut.-Colonel W. H. L. McCarthy, D.S.O., M.C., M.D., second deputy coroner for South-East London, has succeeded the late Mr. A. W. Mills as coroner to the King's Household.

Dr. Strohl, professor of medical physics in the Paris Medical Faculty, has been elected a member of the Académie de Médecine in place of the late Dr. Hanriot.

The Dutch Institute for Pharmacotherapeutical Investigation has issued a report, which is published as a supplement to the *Nederlandsch Tijdschrift voor Geneeskunde*, for February 17th. It contains an account of the composition of a number of secret remedies.

According to the *Journal of the American Medical Association* of January 27th the percentage of illegitimate births in 1932 was 14.1 in Sweden, 12.1 in Germany, 10.7 in Denmark and Czechoslovakia, 8.4 in France, 7.1 in Norway, 4.9 in Italy, 4.6 in Great Britain, 4 in Bulgaria, and 1.4 in Greece.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and **LETTERS** forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Of their articles published in the *British Medical Journal* communicate with the Financial Secretary, British Medical Association House, Tavistock Square, W.C.1. receipt of proofs. Authors overseas if reprints are required, as proofs are

not sent abroad.

All communications with reference to **ADVERTISEMENTS**, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBER** of the British Medical Association and the *British Medical Journal* is **EUSTON 2111** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Aitology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent, London.*

MEDICAL SECRETARY, Medisecra Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Vomiting after Appendicectomy

"**PERPLEXED**" (Paisley) writes: A lady patient of mine, aged 30 years, unmarried, had her appendix removed about two years ago owing to persistent right iliac pain. At the operation the organ was found to be definitely diseased, being abnormally long, thickened, and kinked in places. The operation has certainly relieved her of all pain, but soon afterwards she began to vomit *during* every meal, and has done so ever since, with the result that she is now much underweight. Consequently, she is unable to take a meal in public, or leave her own home on holiday. X-ray examination of the abdomen by a series of plates has failed to reveal anything abnormal, and medicines have afforded her no relief whatever. She has been seen by two consultants, from whose treatment she has derived no benefit at all. Any suggestions will be much appreciated.

Cracked Tongue

"**CEYLON PRACTITIONER**" asks for suggestions in the treatment of a man of about 28 years with cracks on his tongue of over seven years' duration. The cracks are painful. He complains of burning sensations at the pit of the stomach, and of flatulence. The bowels are regular, and the stools, to the naked eye, are not abnormal—nothing in the shape of typical sprue stools. No history of syphilis. There are so far no signs or symptoms characteristic of sprue, and the patient, apart from the condition mentioned, is in good health and attending to his professional duties. He has had various treatments, such as parathyroid extract and calcium, milk diet and fruits, liver treatment, ventriculin, and fermented toddy (a local preparation of yeast), but none of them rid him completely of his condition. Whenever it becomes worse he goes on liver diet, which leads to improvement but does not cure. No analysis of gastric contents or biochemical examination of stools has been made, because laboratory facilities are not available.

Tobacco Habit

"**X Y Z**" writes: Can any of your readers suggest a remedy for excessive smoking? My patient is a young man of 23, and I have tried everything I can think of.

Income Tax

Various Deductions

"**JODDLES**" inquires with regard to some points which will be sufficiently clear from the following reply.

* Subscriptions to the B.M.A. or a medical defence society are allowable expenses, whether incurred on behalf of the principal or assistant. Interest payable on loan—for example, to an insurance company—is not deductible; the payer has the benefit of deducting the tax from the interest at the time of payment. If, however, the interest is paid to a bank, tax cannot be deducted, and the interest is an allowable expense. If the practitioner's wife did, in fact, assist in the work of the practice, and did receive "a

salary of £50 per annum" for so doing, that sum can be claimed as a professional expense. If the claim was not made when the return was made it can be claimed later on the ground of "an error or mistake" in the return; but the fact that it was not made at the proper time may raise some question as to whether the payment was a professional and not a domestic one.

LETTERS, NOTES, ETC.

Lumbago and Quinine

Lieut.-Colonel CHARLES H. BARBER, I.M.S. (ret.) (Florence), writes: No mention is made, in the books I have at hand, of the use of quinine in lumbago, and I have no knowledge of its use by other medical men, so that it seems worth while to draw attention to its value. In India, with the thought at the back of my mind of a possible malarial origin of the trouble, I have on occasion treated cases by the oral administration of 15 or 20 grains of quinine hydrochloride per diem and have found it to act surprisingly well. Recently, after a month's suffering and after using aspirin and the usual remedies with no effect, I tried quinine on myself, with the result that within a few hours I was relieved, and in four days practically free of pain and disability, although other conditions were unchanged. I may add that I suffered from lumbago long before I went to India, and also that whilst there I had malaria only very slightly and on rare occasions.

Herpes and Varicella

Dr. R. WHITTAKER (Weymouth and District Hospital) writes: In connexion with the recent correspondence about the relation of herpes zoster to varicella, a household I attended as locum tenens in the Isle of Man may be of interest. I was originally called to see the father, a man of about 40, with severe herpes of the left trigeminal region and geniculate herpes on the same side. Four days after I first saw him his two children developed typical varicella, and on the sixth day I found he had it himself, as well as the herpes. The chicken-pox rash cleared up very quickly, but the herpes was still very marked when I last saw him, a fortnight after my first visit.

Road Dangers

Dr. GEORGE JONES (London, S.E.13) writes: If something is not done, and that very soon, the roads will be completely blocked up, and neither pedestrian nor motorist, quick drivers or slow, will be able to use them safely or at all, except with great loss of time. Traffic blocks, even in suburban London, are becoming worse and worse. They seem to be due largely to lorries of ever-increasing size, with trailers behind them, and to motor coaches, whose length rather than breadth seems excessive. I have seen lorries whose bodies extended a good foot over the wheels passing quite close to the edge of the pavement. It is not needful to send tons and tons of bricks or paving stones by road, and passengers can be carried quite easily by rail, especially from long distances. Parliament imposed stringent conditions on the railways: if it does not do something more for all classes of road users we shall find ourselves worse and worse off year by year.

Corrigendum

GLAXO LABORATORIES (London, N.W.1) ask permission to correct a mistake which occurred in their advertisement of March 3rd. The mistake (for which they accept sole responsibility) occurred in the last paragraph but one of the second column of their advertisement. "Sunshine Glaxo is enriched by 200 and Full Cream Glaxo by 165 international units of this essential body-building anti-rachitic factor" should read: "Sunshine Glaxo is enriched by 200 and Full Cream Glaxo by 165 international units, per pint reconstituted, of this," etc.

The British Drug Houses Ltd. have just issued a priced catalogue of preparations for parenteral administration, arranged in alphabetical order. Practitioners can obtain a copy free of charge on application to this firm, Graham Street, City Road, London, N.1.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 39, 40, 41, 42, 43, and 46 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 44 and 45.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 96.

THE CAUSES AND TREATMENT OF ARTHRITIS*

BY

CHARLES W. BUCKLEY, M.D., F.R.C.P.

PHYSICIAN TO THE DEVONSHIRE HOSPITAL FOR RHEUMATIC DISEASES, BUNTON; MEMBER OF THE
BRITISH MEDICAL ASSOCIATION ARTHRITIS COMMITTEE

In the report of the B.M.A. Arthritis Committee a classification¹ was adopted differentiating on broad lines rheumatoid arthritis and osteo-arthritis. This differentiation is of the utmost importance from the point of view of aetiology, prognosis, and treatment, and as the subject is so wide I shall limit my remarks to the treatment of rheumatoid arthritis alone. This has been subdivided into primary and secondary; in the former no focus of infection can be found; in the latter such a focus can be identified and should be dealt with as radically as possible, with due regard to the general condition of the patient. It is essential to remember that wholesale extraction of teeth or enucleation of tonsils may be accompanied by as much shock as a major operation, and resistance may be so much lowered by such a procedure that the disease gains a firm hold, and the patient's condition is worse than before. This disastrous result may be, in some measure, caused by the liberation of toxins and micro-organisms in great amount, and their entrance into the general circulation. I shall not attempt to enumerate the many possible foci from which infection may proceed, but would stress the fact that the existence of a focus needs to be associated with other factors before infection spreads to the joints or other tissues. The soil is, in fact, as important as the seed. Heredity is a factor in about 50 per cent. of cases, and the bodily characteristics are a slight, spare physique, the patient often being emotional and lacking in endurance, with poor circulation, cold extremities, and a liability to chilblains. This is probably the outcome of endocrine influences, with sympathetic instability and defective calcium assimilation. You will note the resemblance to the type of individual prone to tuberculous infection, and the close analogy between arthritis and tuberculous disease is a feature to which I shall have occasion to return.

We have, then, two aetiological factors—soil and seed; and there is a third in external influences, such as excessive fatigue—mental or physical—emotional strain, or shock. The combination of cold and damp with unfavourable hygienic conditions depresses resistance to disease generally, though arthritis is by no means a slum disease, and is met with in all classes. Local as well as general influences play a part, and in the less severe types it is noticeable that the joints first affected are those which are most subjected to strain or which have been the seat of injury. The small proportion of so-called primary cases are almost entirely confined to the female sex, and in these, although no focus of infection can be detected in the light of our present knowledge, it seems not unlikely that here also there is a microbic factor which has by some means obtained access to the system.

A French authority¹ has recently criticized severely the doctrine of focal infection and the operative treatment of foci. He admits that cure sometimes appears to follow the eradication of septic foci, though in other cases no such happy result ensues; while there are also instances of the arthritis being cured or, it may be, dying out in spite of the continued existence of such foci. He furthermore denies that there is any proof that the streptococci, commonly regarded as the cause, are anything more than common saprophytes; and, while admitting that a focus of infection may serve as a portal of entry for whatever germ may be responsible for the arthritis, he asserts that we are completely ignorant of its nature. He agrees that

it is sound practice to deal with infective foci in order to put the system into a better state of defence against the infection, whatever it is, and that the extraction of septic teeth, etc., is, for this reason, equally indicated in a case of gonococcal arthritis. While these views will not be accepted in their entirety by workers of experience in this country, they point an important moral—namely, that the treatment of septic foci should be carried out with the aim of improving the general health and never in such a way as to weaken the patient or reduce the powers of resistance through the shock of extensive surgical procedures. In the primary form, attention to the general health and mode of life is of equal importance, together with treatment of endocrine deficiencies so far as may be possible; in other respects the principles of treatment for both forms will proceed along the same lines, for there is a strong probability that as our knowledge increases the distinction between the two forms will cease to be made.

ROLE OF THE STREPTOCOCCI IN ARTHRITIS

Opinions vary widely as to the form of streptococcus which is the probable cause of arthritis, and as to whether other microbes may not be equally incriminated. If we admit that the case against the streptococci—haemolytic, anhaemolytic, or *viridans*, to name the three types most commonly met with in septic foci associated with rheumatic disorders—may not be completely proved, it will still be advisable to look upon them with grave suspicion, and, therefore, to consider the evidence. We are at once faced with the doubts which are arising as to the differences between these three types. Besredka² states definitely that it has been established that a streptococcal infection can take on different clinical forms according to the individual resistance of the subject and according to the ultimate structure of the inoculated region, quite independently of the nature of the streptococcus or of its original source. He holds that the streptococci met with in scarlet fever, for example, may belong to several varieties; and, on the other hand, the same variety of streptococcus may be met with in diseases clinically different. He further asserts that demonstrating by means of the microscope the presence of streptococci in the course of an infection is not enough to enable us to conclude that it is a streptococcal illness, a truism which seems sometimes to be forgotten.

Recent researches indicate that there are many culturally different strains of streptococci which may be concerned in the aetiology of rheumatic conditions, that laboratory and cultural distinctions are of less importance than has hitherto been supposed, and that some character common to them all is the important factor in producing tissue reactions of rheumatic type. Some workers believe that it is possible, by suitable cultural methods, to change a haemolytic streptococcus into the *viridans* type, and thence into the anhaemolytic form. There is also evidence that some, at least, of the diphtheroids which are so frequently met with in cultures from the tonsil may be streptococcal variations. If these changes should be proved our views of the relation of streptococci to certain pathological processes must undergo profound modification. It seems to me also not unlikely that a streptococcus may be modified in its characters and effects, not only by the tissues in which it grows, but also by other micro-organisms which are present in the same focus. It is very usual to find the *Streptococcus viridans* associated

*Address to the Halifax Division of the British Medical Association, November 8th, 1933.

with the *Staphylococcus aureus* as well as with many other microbes. If we accept the view, as I think we must, that rheumatoid arthritis is commonly associated with the presence of a septic focus and that such focus always contains micrococci of one type or another, the question arises: Do these microbes set up the arthritis, and, if so, how?

Rosenow³ believes that certain strains of streptococci have a special affinity for joints or connective tissues, and that such affinity may be developed by repeated passages *in vivo* in rabbits' joints or by other methods; these strains have been termed "arthrophile." His views are not universally accepted, but cannot lightly be set aside. Of more serious moment are the arguments which seem to be gaining ground that the arthritis which some workers claim to have produced in rabbits by the injection of streptococci does not possess the character of a true rheumatic granulomatosis, but is an ordinary septic arthritis. Magrassi,⁴ who holds this view, claims to have brought about true rheumatic lesions by injecting haemolytic streptococci from rheumatic fever into a joint; a focus is thus formed, and sensitizes certain tissues by means of substances which enter the circulation from it. After an interval of time these substances act as provoking material, and set up local inflammatory reactions or lesions of true rheumatic type. He notes that in such states the intravenous injection of streptococcal antigen will provoke or increase such effects. Although his work has been concerned with rheumatic fever, it seems to have a definite bearing on arthritis. The silent period which has been shown by Glover and others to elapse between an attack of tonsillitis—formation of a focus—and the development of an attack of acute rheumatism seems to find an explanation in Magrassi's work. There is considerable evidence in support of the view that the joint and other lesions of rheumatic fever, and also of acute infective or rheumatoid arthritis, are due not to the actual presence of the infecting micro-organism itself in the affected tissues, but to allergic effects. The classical example of allergy in joints is one which many of you will have seen—namely, the arthritis which sometimes follows the injection of horse serum in the form of antitoxin. These allergic reactions may result in animals sensitized to them from the injection of suspensions of streptococci killed by heat, and are analogous to the tissue reactions of rheumatism; but they occur in experimental investigation only in places where an allergic "phlogosis" has been provoked by the introduction of antigen. Swift, Derrick, and Hitchcock,⁵ prominent American workers on this subject, say:

"There is much clinical evidence to support the contention that focal infection has an important bearing on the evolution of this [rheumatic] disease, but up to the present the importance of the focus was thought to rest in its role as a nidus from which the virus was disseminated throughout the body. Our conception of the focus, on the other hand, is of an area where the allergizing substance is produced and whence it is spread to sensitize the various tissues. This conception does not deny that virus may also gain entrance to the blood stream from the focus, but stresses the allergizing effect."

They also observe that "inoculation with non-haemolytic streptococci produces a hyperergic condition and increased susceptibility, not only to the same strain, but also to more distantly related strains."

From these and many other observations on similar lines has developed the theory that a septic focus continually passes into the blood substances which act upon certain tissues for which they have a predilection in such a way that these tissues become sensitized. Sooner or later a heavy dose is absorbed, or the endocrine defences break down, or the local or general resistance is reduced by one of the many causes already referred to, and inflammation results—an arthritis or fibrositis. This

appears to explain adequately the joint lesions of acute rheumatism or the connective tissue reactions of fibrositis, but whether it is sufficient to explain the persistent and progressive lesions of rheumatoid arthritis without the actual presence of the infecting micro-organisms in the joint tissues is not so evident. In this connexion it is necessary to mention the recent work of Cecil, Nicholls, and Stainsby,⁶ who, by a special technique, have succeeded in growing a streptococcus from the blood. Their work has yet to be confirmed by other observers, but the fact that the organism requires fifteen days to grow suggests that its virulence is low, and strengthens the idea that presensitization of the tissues is essential if it is to exert any pathogenic action.

RHUMATISME TUBERCULEUX

Some Continental authorities, especially in France, believe that there is a type of rheumatoid arthritis which is tuberculous in origin. It is claimed that filter-passing forms of the bacillus of Koch have been discovered in these cases. Where a polyarthritis occurs in conjunction with other lesions more generally recognized as tuberculous it is difficult to deny that the joint lesions may also be of that nature. It is claimed, however, that cases of acute polyarthritis resembling acute rheumatism but resistant to salicylates and free from cardiac complications, tending to persistent hydrarthrosis or passing into a chronic polyarthritis, are often tuberculous. Cases of this type in this country are not differentiated clinically from ordinary rheumatoid arthritis, though a few English physicians speak of the Poncet type, after the French physician who first advanced this view. It cannot be denied, however, that the constitutional type and the symptoms, apart from the actual arthritis, are in many cases similar to those of tuberculosis, and that the same general principles of treatment are often indicated. I have examined many cases of this nature without finding evidence of tuberculosis elsewhere, and the von Pirquet and Mantoux tests have proved negative; nor has it fallen to my lot to see any of the cases develop frank tuberculosis. Some of them, however, have given positive reactions to the intradermal vaccine of Ponnendorf, without any sign of awakening tuberculous foci elsewhere in the body. Ankylosing spondylitis has also been claimed to be tuberculous, but in this condition also, although its victims are commonly of the tuberculous type, I have not yet been able to satisfy myself that the special lesions were tuberculous; in fact, they are in sharp contrast to the typical appearance and course of tuberculous caries of the spine.

Whatever may be the ultimate outcome of all these theories, one thing at least seems clear—namely, that acute rheumatoid arthritis is usually associated with the presence of septic foci in the body, and presumably is caused by one or more of the micro-organisms therein. Such foci must therefore be the first object of treatment. We must next consider how we may combat the invasion of the system and the joints especially, remembering that in the more acute forms of arthritis there is ample evidence of general constitutional illness, of which the joint lesions are the most obvious.

VACCINE THERAPY

The question of vaccine treatment may first be considered. It has had a great vogue, but now the pendulum is swinging in the other direction. The success of vaccines in prophylaxis in many diseases led to high hopes that they would be equally successful as a method of treatment, and they have been employed more extensively in chronic rheumatic disease than in any other condition. Faced with a disease which so often pursues

a steady downhill course the doctor is naturally glad to try any remedy which offers a promise of helping in the fight, especially if it appears to have a scientific basis. Unfortunately the purveying of vaccines has, to a great extent, become commercialized, and the art of advertising has done something to extend their use. From my own observation I should say that there have been more cripples than cures following the injudicious, uninstructed, and often haphazard administration of a remedy which with care and skill has sometimes proved of great value in my own experience and in that of many others.

In the leading textbooks on the subject there is a marked lack of enthusiasm. Freund,⁷ a prominent Vienna authority, in his *Gelenkerkrankungen*, states definitely that he has found no marked differences between the results from vaccine treatment and from non-specific methods. Thompson and Gordon⁸ say that the most that can be expected from vaccines is that they should act as adjuvants to other forms of treatment. They point out that they sometimes appear to be remarkably effective and at other times, in cases apparently identical, there is no benefit whatever. In some instances there is marked reaction to small doses, and in others a large dose produces no reaction at all, making it difficult to give any guidance in treatment. They regard local reaction in the joints as the best guide, and advocate the smallest dose that induces such a reaction. Pemberton⁹ quotes Kolmer, an American authority on immunology, and agrees with his opinion that vaccines made from septic foci, joints, etc., have not given encouraging results. He also advises that, where there is local reaction in the joints, the dosage should be small and continued over a long period of time. He holds the view that the effects may be non-specific in great measure. Congdon,¹⁰ in a close statistical analysis of 330 cases of secondary rheumatoid arthritis treated with vaccines in the Devonshire Hospital, Buxton, found a difference of 13 per cent. in favour of cases treated with vaccines. She also showed that stock vaccines gave as good results as autogenous ones: this is opposed to the view of specific therapy. Coste,¹¹ after denying that there is any conclusive evidence that the strains of streptococci commonly incriminated have any aetiological relation to arthritis, states as his opinion that all the so-called specific vaccines for arthritis, with the possible exception of gonococcal vaccine and tuberculin, act only by setting up protein shock, to which arthritides are very susceptible. He expresses doubt even as to the specific effect of gonococcal vaccine in the arthritis of this disease, and suggests that its frequently beneficial action may be owing to some non-specific factor, illustrating this by observations on cases of arthritis which were certainly not of this nature, but which were definitely benefited by gonococcus vaccine. Warren Crowe,¹² an enthusiastic believer in vaccine therapy in arthritis, claims remarkably good results. He is of the opinion that a micrococcus closely allied to the common skin staphylococcus is a factor in the production of rheumatoid arthritis, and employs a vaccine of this organism as well as a mixed vaccine from a great number of strains of streptococci. He advocates very small doses, closely regulated by the reactions produced. Cronin Lowe¹³ and other workers have devised what they term the "pathogen selective" method of vaccine therapy. Inoculation of material from the suspected focus is made into the patient's own blood, the theory being that those organisms which survive and are grown on subsequent cultivation are those to which the blood is lacking in protective substances. Apart entirely from the question of vaccine therapy, this procedure seems likely to throw light on the specific character of the microbes in the focus and possibly also on the nature of the infective agent in arthritis.

RATIONALE OF VACCINE THERAPY

The principle involved in injecting a vaccine is generally held to be the stimulation of the formation of antibodies, with the object of strengthening the natural resistance against a specific infection. It is easy to see the preventive value of such a measure, as in the case of inoculation against enteric fever, but the problem becomes far more difficult when it is proposed to use such a vaccine as a method of treatment during the actual course of any disease, when the system is already invaded by the specific micro-organism and its toxins, against which the defensive forces of the body are already fully mobilized. Hence, vaccines are employed for curative purposes in comparatively few diseases caused by a specific micro-organism, and even in those their value is not universally admitted, and is, indeed, often denied. On the face of it, it would seem illogical, when there is already an invasion of a living and toxin-producing microbe, to inject into the system a series of further doses of the same microbe, even though dead: the dead bodies contain the endotoxin, and in some forms of vaccine the exotoxins are also present. Yet there is clinical evidence that cure has at times followed this line of treatment, and thus, in the case of arthritis, there are enthusiastic advocates of vaccine therapy and others who condemn it with equal energy. It seems probable that it is not a simple matter of antibody formation. Besredka¹⁴ says definitely that vaccine therapy does not depend on the elaboration of antibodies. To quote his words:

"There are few pathogenic microbes which are as bad producers of antibodies as the staphylococci. However, the clinicians affirm—with a unanimity to which they are but little accustomed—that they know no recoveries more striking than those obtained by vaccino-therapeutic treatment."

His sarcasm at the expense of clinicians may with force be applied to the bacteriologists, for they are sadly lacking in unanimity in the advice they give us. In this problem, as in many others, there is urgent need for more effective liaison between the bacteriologist and the clinician. The former is a rare visitor in the wards, and the latter is not always welcomed in the laboratory; yet the practical value of bacteriology must depend upon the close association of clinical observation with laboratory investigation. Only then will it be possible to lay down with any certainty the proper procedure in treatment, and to decide whether specific or non-specific therapy is likely to yield the best results.

In the face of these considerations it seems to me that we should employ vaccines of specific type only when an infective focus has been identified and eradicated. We can ignore, I think, the possibility that the infecting organism has become an inhabitant of the bowel, for there is sufficient evidence that bacteria do not normally enter the circulation from this source; and the toxins, if absorbed, are probably greatly modified, if not destroyed, by passing through the lines of defence. In such a case we can give vaccines with reasonable confidence, since the supply of the infecting material from the focus has been cut off and we are stimulating the defences of the body without the risk of increasing toxic reactions. Autogenous vaccines may here be the most advantageous, but they must be started in small doses, their effects closely watched, and dosage and interval regulated accordingly. If there is any marked reaction in the joints, or any pyrexial effect, doses must be reduced and intervals increased: such phenomena are likely to be caused by the existence of some unsuspected secondary focus, for which search must be made. An important aspect from the practical point of view of the allergic theory is that, the tissues being sensitized to the toxins, a process of desensitization is indicated. As asthma

and hay fever, due to pollens or other non-living substances, are treated by injection of minute doses of the specific substance in order to desensitize the tissues, so may arthritis on the same grounds be treated by vaccines. This is the view of those who believe in extremely small doses, which sometimes, curiously enough, are attended by reactions as definite as those from doses, it may be, a hundred times as great.

PROTEIN SHOCK

How far are vaccine effects the result of protein shock is the problem which must next be faced. That arthritides have a heightened susceptibility to this has already been mentioned, and the view held by some is that any benefit following vaccines is of this nature. Protein shock induced by non-specific vaccines such as T.A.B., or by the injection of milk, casein, and other special non-bacterial substances such as bee stings, has been tried extensively: in this category must also be placed autohaemotherapy. Such procedures often give good results, but perhaps oftener fail, or relapses occur; as they are apt to be attended by shock, sometimes severe and always attended by risk, the more drastic of these methods are falling into disuse. The employment of stock vaccines as a method of protein shock therapy is less open to objection, and also has the advantage that, if the specific microbe is present, it may assist by more direct action. On this principle stock vaccine may be used where a focus is still thought to exist, but with the same precautions as have already been mentioned for autogenous ones. If favourable results are likely to accrue there will soon be signs of this, and if improvement is not quickly seen it is doubtful policy to persevere with the vaccine.

INTRADERMAL VACCINATION

While vaccines are generally administered by the subcutaneous or intramuscular route, there is another method—namely, intradermal inoculation—which is of proved value in some other bacterial infections, and which is believed to act by stimulating the formation of protective substances from the fixed cells of the deeper layers of the dermis. This has been tried in arthritis, but has not so far been strikingly successful; it is, however, safer, since absorption is slower, and it is an important feature in a method which is widely employed in France and for which much is claimed, not solely on account of the way of administration, but also because of the vaccines used—the Ponndorf vaccines. These vaccines are of three types: A, which is derived from bovine tubercle with some proportion of an autolysate of Koch's bacillus; B, which has A as a basis, with the addition of autolysates of staphylococci, streptococci, pneumococci, and the bacillus of Pfeiffer; and G, which contains, in addition to B as a base, an autolysate of the gonococcus. All are administered by scarifying the skin and rubbing the vaccine into the scarified area, much as in ordinary vaccination. In rheumatoid arthritis B is indicated, and may give rise to three types of reaction: (1) local, which may vary from slight redness up to a free serous exudation and formation of a scab; (2) general, which may be absent or severe, with a rise of temperature lasting for a few days; and (3) focal, an increase in the joint symptoms which, when it occurs, is of good augury.

While some French writers are enthusiastic over this treatment it has not had the same success in the hands of other workers. Personally, in a not very extensive trial, I have had some positive results and some negative; I propose to continue its use in suitable cases. (There is a similar preparation, milder in its action—the vaccine of Paul.) It is wise to examine carefully for any tuberculous lesions, active or quiescent, which are generally

held to be a contraindication to the method. It is interesting to note that an English physician, Copeman¹⁷ adds to the vaccine he employs in some cases a small proportion of tuberculin as a universal non-specific antigen.

CHRYSOTHERAPY

Chrysotherapy as a way of treating arthritis has recently come into fashion, and is being widely resorted to on the Continent, though, as yet, but little in this country. Coste¹⁸ asserts that it is the most important addition which has been made for a long time to the therapy of chronic rheumatic diseases. We owe much of the work on the subject to Forestier,¹⁹ who, observing the similarity between tuberculosis and arthritis, conceived the idea of treating cases of chronic polyarthritis with the salts of gold, which were being therapeutically applied in the former disease. His first publication was an account of forty-four cases, with seventeen very good results, sixteen good results, ten moderate, and only one negative.

Several compounds have been tried, but chiefly allochrysin (an organic compound of gold and sulphur, with sodium) in France, and solganal B (a compound of gold, sulphur, and glucose) in Germany. I have used allochrysin in a certain number of cases with some promising results, but the number is not yet sufficient nor have they been under observation long enough for me to quote my own experience. The salt is given by the intramuscular route; 5 centigrams are given at weekly intervals and the doses are increased cautiously; the treatment is not notably painful. After about twelve weeks, or when a total of 1.5 to 2.5 grams have been given, an interval of six weeks must be allowed for elimination, as the salts of gold are cumulative in the system. Improvement sometimes does not show itself during the first course, and a second or third may be required before a positive opinion can be formed. The first sign is improvement in general health, followed by diminution of articular swellings, but pain on movement may be diminished much earlier than this, as tested by the amount of aspirin or other analgesics required. In favourable cases the anaemia lessens and the sedimentation rate tends to alter in the direction of normal—an important test.

The principal effects which may result from overdosage or indicate intolerance are: (1) a rise of temperature of half a degree or more, rarely of two or three degrees (which occurred in one of my cases, but was followed by a marked improvement)—this pyrexia is usually confined to the first dose, and if it continues it indicates intolerance; (2) skin eruptions of scarlatiniform or morbilliform type, fleeting in character, and with some itching—this appears to be an anaphylactic reaction, and does not contraindicate treatment. Later symptoms may be a metallic taste, and if this is neglected stomatitis may follow; the treatment must be temporarily abandoned, or this may become severe. Skin eruptions of a more severe type, and glandular enlargement, may arise. In a few cases albuminuria has been noticed, but almost all these complications followed a dosage much greater than I have mentioned. They indicate, however, the desirability of proper dental toilet and of testing the renal functions beforehand.

Of solganal B I have no personal experience: it is said to be less toxic and of higher therapeutic effect. It has been given by the mouth, and good results are claimed for this method. Skin eruptions may be met with, and one notable symptom as the dose approaches a maximum is fatigue, more or less pronounced, and accompanied by loss of appetite. The focal reactions to the first dose may be more marked than with allochrysin. It is well to examine the blood for any sudden variation in the

number of leucocytes—a fall in polynuclears especially is an indication to reduce the dose or to suspend treatment. The urine must also be watched for signs of renal irritation. It is necessary to stress the fact that this line of treatment is in its infancy, and needs much careful observation before exact procedures can be laid down.

Recognizing the possible ill effects, one can say that they are no greater than those which accompany vaccine therapy, protein shock, or other methods, and in view of the grave prognosis in untreated cases we are justified in taking some risk, just as the surgeon must regard risks as inseparable from operative measures. The part played by sulphur in these compounds is of interest, as it would appear to increase the activity of the gold acting synergically. This is probably its action when administered independently, as a mineral water, an organic sulphur compound, or otherwise, activating other substances.

IODINE AND CALCIUM

Iodine is a remedy widely employed, and sometimes beneficially. It may be given as the alcoholic solution (thirty grains in an ounce of rectified spirit is a useful prescription), beginning with one drop in milk three times a day and increasing gradually to five or more, with occasional intervals. Or one of the colloidal forms, such as collosol iodine, may be prescribed. The fatty compounds present some advantages, and I have found lipiodol a good one, injected intramuscularly. Compounds of iodine and hexamine are in common use abroad, but I have no experience of them. Iodide of iron with arsenic is a valuable tonic in arthritis.

Calcium is now extensively given because of the evidence of defective calcium metabolism as shown in radiograms by increased transparency of the bones. It is likely that its action is by no means limited to replacing calcium wastage in the bones, and the vogue which the calcium-containing mineral waters have had for centuries for the treatment of rheumatic diseases is suggestive. The intake of calcium in ordinary diet is probably adequate, but the cells appear to have lost their power of assimilating it; it may be that in mineral waters other constituents, such as radon, act by increasing this assimilation in the same way as the action of sulphur already referred to. It is also desirable to include vitamin D in the form of cod-liver oil or its concentrates to promote assimilation of calcium, or to attain this object by means of exposure to ultra-violet rays.

Many other remedies have been tried in this intractable disease, but time will not permit me to discuss them further. In particular, I regret having to omit all reference to mineral waters and other hydrological methods, and to physical methods of treatment in general, which many authors regard as at least as valuable as vaccines or any other form of internal medication; but you will find these dealt with in the B.M.A. report.

TREATMENT OF MALARIA IN EUROPEANS BY ATEBRIN

WITH SPECIAL REFERENCE TO THE RELAPSE RATE

BY

P. D. JOHNSON, M.R.C.S., L.R.C.P.

MEDICAL OFFICER, BATU GAJAH, PERAK, F.M.S.

Between June, 1932, and June, 1933, forty-nine European admissions to Batu Gajah Hospital with malaria have been treated by atebtrin uncombined with any other specific antimalarial remedy. As all but three of these cases have been followed up for periods ranging from two months to over a year, it has been possible not only to observe the immediate effects of treatment, but also to test the value of this new chemotherapeutic discovery in preventing relapses, for it is in this respect that the greatest claims have been made for atebtrin. Of these forty-nine cases, twenty-nine were diagnosed microscopically as benign tertian, seventeen as subtertian, and three as mixed tertian malaria. Atebtrin was given in the form of 0.1 gram tablets three times a day between meals, children receiving a proportionately smaller dose. The total adult dose varied between 1.4 and 2.4 grams. Complete rest in bed was maintained for forty-eight hours after the termination of the febrile period, and, apart from a preliminary dose of calomel, a daily saline purgative, and aspirin during the "hot stage," no other drugs were prescribed as a routine.

IMMEDIATE EFFECTS OF TREATMENT

Compared with eighty-three European cases treated between June, 1931, and June, 1932, by quinine, plasmoquine, and alkalis, the treatment by atebtrin has proved very satisfactory. A large proportion of the quinine-treated subtertian cases were given intramuscular injections on account of vomiting, but in only one instance had this to be resorted to in the atebtrin-treated cases. It may be that a particularly mild type of infection was encountered in the 1932-3 series, but the impression remains that quinine by the mouth very frequently excites vomiting. In both series subtertian malaria took rather longer to control than benign tertian, but atebtrin seemed superior in this respect to quinine. It was found comparatively pleasant to take, and did not cause any of the neurotropic symptoms so frequently associated with quinine. For this reason it was particularly valuable in children, who tolerated doses rather larger than those usually recommended. One infant, aged 8 months, was given 0.1 gram daily for five days without any ill-effects. Many patients expressed a feeling of well-being during treatment, and those with previous experience of quinine were unanimous in their preference for atebtrin.

Malaria complicating pregnancy was treated in three cases by quinine and in two cases by atebtrin. On no occasion did quinine or atebtrin appear to have any deleterious effect on the pregnant uterus. One patient with an idiosyncrasy to quinine developed urticarial and pseudo-asthmatic symptoms after 5 grains, but was able to take a full course of atebtrin without any ill effects. A comparison between the duration of the pyrexial period and the persistence of malaria parasites in the blood after the beginning of treatment is given in Table I. The quinine-treated cases received 2 grams of quinine and 0.01 gram of plasmoquine daily.

As far as the immediate treatment is concerned, it would appear from these figures that atebtrin is superior to quinine in controlling the temperature and ridding the blood of parasites in all types of malaria, but particularly so in subtertian infections. Its occasional provocative effect on the parasites of subtertian malaria will be discussed later.

Q = Quinine.

A = Atebrin.

TOXIC SEQUELAE OF TREATMENT BY ATEBRIN

The yellow discoloration of the skin which occurred in a large proportion of European cases cannot be regarded as a sign of toxicity, but is due to the staining properties of the drug. It is more common in fair-skinned Europeans than in Asiatic. Green¹ recorded it in only seven out of fifty Asiatic cases. In our series of Europeans it did not appear as a rule until the fourth or fifth day of treatment, and in some instances not until a week or more after leaving hospital. It is of interest to note that in one patient having jaundice on admission to hospital bile disappeared from the urine while full doses of atebtrin were being taken.

The toxic symptoms attributed to atebtrin by various observers are "light-headedness," headache, and epigastric pain. In none of our patients was the first apparent, but one female patient complained of severe headache after a course of 1.6 grams. No patient suffered from abdominal pain during treatment, but six experienced it after leaving hospital. This amounted to slight indigestion in four cases, each of which had received 1.3, 1.5, 2.1, and 2.4 grams of atebtrin respectively. In the other two cases the condition was more serious; in both the onset of pain coincided with a yellow skin discoloration, which disappeared respectively a week and a fortnight after completing treatment. Both patients had received a total dose of 1.5 grams. The pain, which was confined to the epigastrium, was made worse by taking food, but there was no vomiting. A milk diet for a few days combined with alkalis caused a rapid cessation of the pain, which has not recurred. This delay in the appearance of toxic symptoms illustrates the cumulative action and slow excretion of atebtrin.

Atebrin, like plasmoquine, appears occasionally to have a provocative effect on subtertian parasites during the first forty-eight hours of treatment. One female patient with subtertian malaria became definitely worse after the exhibition of 0.4 gram. She had a feeling of impending dissolution, and showed signs of collapse. After an injection of quinine and adrenaline, atebtrin was continued in small doses without any further ill effects. She has had no relapse since. In three patients with negative blood films on admission to hospital parasites appeared in large numbers in the blood only after 0.6 to 0.9 gram of atebtrin had been taken.

COMBINED COURSE OF ATEBRIN AND PLASMOQUINE

Apart from other considerations it was felt that, as the purpose of this investigation was to test the effect of atebtrin on malaria, the addition of plasmoquine would stultify the value of any results that might be obtained. Several cases, however, were admitted to hospital as a result of this treatment.

Case 1.—A male European took four tablets of atebtrin and plasmoquine daily for two days. He was admitted to hospital with severe epigastric pain and vomiting. There was pronounced yellow staining of the skin and conjunctivae, and the lips were cyanosed. Subtertian parasites were present in the blood. The urine contained albumin, granular casts, and red blood cells. Atebrin was continued cautiously without any further ill effects till a total of 1.5 grams had been taken. He relapsed, however, within one month of leaving hospital.

Case 2.—A female European was admitted after taking twelve tablets of atebtrin and twelve of plasmoquine (three of each daily), with dyspnoea, cardiac distress, and a feeling of constriction of the jaws and pharynx. There was well-marked cyanosis of the lips and nails. Nothing abnormal was detected in the urine, and the blood, which had not been examined prior to treatment, was negative for malaria parasites.

Case 3.—A male European was admitted to hospital with abdominal pain and vomiting following a total dose of 1.2 grams of atebtrin and 0.08 gram of plasmoquine. There was the usual intense yellow staining of the skin. The blood and urine were negative. He relapsed two months later with benign tertian malaria, and received a five days' course of atebtrin without any toxic manifestations. He has not relapsed since.

In these three cases the total amount of plasmoquine taken would not be expected in itself to give rise to symptoms. It is probable, however, that a combination of atebtrin and plasmoquine is more toxic than either drug alone.

Thonnard-Neumann and Le Doux² found that about half their atebtrin-treated and plasmoquine-treated cases developed abdominal pain, whereas those treated by atebtrin alone were completely free from this disturbance. Duncan³ observed that 14 per cent. of his cases treated by atebtrin and plasmoquine developed abdominal symptoms, while those treated by atebtrin alone did not. In spite of the apparent lower relapse rate in benign tertian malaria after the combined course, he doubts whether such treatment is justified. There is a certain amount of evidence that atebtrin and plasmoquine are more effective than atebtrin alone in preventing relapses in benign tertian malaria. Out of 168 benign tertian cases treated by Duncan with atebtrin 10.7 per cent. relapsed, but he was able to reduce this relapse rate in a series of 116 benign tertian cases treated by atebtrin and plasmoquine to just over 5 per cent. Barrowman⁴ found that, whereas 12 per cent. of his benign tertian cases relapsed after a course of atebtrin, only 3 per cent. did so after atebtrin and plasmoquine. It is interesting to note that a 5 per cent. relapse rate in subtertian cases was unaffected by the addition of plasmoquine.

There would thus appear to be a rational basis for treating benign tertian malaria by the combined course, but it is for subtertian malaria that it is generally prescribed. The reason is, presumably, that atebtrin, like quinine, is believed to have little or no effect on the gametocytes of *P. falciparum*, whereas plasmoquine has a selective action on these forms of the parasite. Plasmoquine, on the other hand, has a very feeble action on the ring forms of subtertian malaria, though it has a definite action on all forms of *P. vivax*. It is known that malaria cannot be transmitted to the mosquito during the first week or ten days of the primary attack, and that only a small proportion of cases have sufficient gametocytes in the peripheral blood to infect mosquitos. Furthermore, Amies⁵ has shown that a dose of 0.04 gram of plasmoquine given twice weekly is effective in preventing crescent carriers from infecting mosquitos.

It follows, therefore, that the use of plasmoquine in benign tertian malaria should be confined to patients under strict observation, so that it can be discontinued if toxic symptoms appear imminent. In subtertian malaria there is no justification for administering plasmoquine during the febrile period; it can do little or no good, and may do harm. It should be employed solely as a gametocide when a clinical cure has been effected.

THE RELAPSE RATE IN EUROPEANS

In Malaya the possibility of reinfection must always be borne in mind when estimating the value of any treatment. The uneducated Asiatic rarely uses a mosquito net or appreciates the part the mosquito plays in con-

veying infection. The educated European, on the other hand, can generally be relied upon to take precautions against infection, especially if he has already experienced the discomforts of malaria. A recurrence of malaria, therefore, in a European within a few months of treatment is more likely to be a relapse than a reinfection, though it must be remembered that in benign tertian malaria a relapse can occur as long as eight months after a primary attack.

1. Quinine-treated Europeans

Of eighty-three cases treated by quinine between June, 1931, and June, 1932, twelve have been followed up for from one to two years, and have had no recurrence of malaria; twenty-four have relapsed clinically and microscopically, and the subsequent history of the remaining forty-seven is unknown. These results are given in tabular form, but owing to the large number of cases not followed up it would be unwise to draw any definite conclusions from them. It is, however, probable that over 60 per cent. of Europeans relapse after a short course of quinine.

TABLE II.—Quinine-treated Europeans

	B. T.	S. T.	B. T. and S. T.	Total of All Types
Number of cases ...	41	34	8	83
Relapses ...	12	10	2	24
Not relapsed ...	3	6	3	12
Not followed up ...	26	18	3	47
Relapse per cent. ...	80	62.5	—	65.6

A study of the relapses after primary infections is interesting, as it shows that 100 per cent. of subtertian relapses and over 50 per cent. of benign tertian relapses occur within two months of treatment. This is best shown diagrammatically.

FIG. 1.—Quinine-treated cases. Showing the period in months after a primary attack when relapses usually occur.

If these figures, based on a few cases, are correct for the majority, it follows that in estimating the relapse rate in subtertian malaria it is only necessary to follow up cases for two or three months, whereas in benign tertian malaria a much longer period is required, though three or four months is long enough to give a good indication of the results of any treatment.

2. Atebrin-treated Cases.

Out of the first 100 Asiatic cases treated in Batu Gajah Hospital by atebrin alone between June and December, 1932, twenty were kept under observation for four months, during which period only one relapsed. This relapse rate of 5 per cent., though calculated on too small a number to be accurate, agrees with the published figures of other observers in Malaya. R. Green⁶ in Kuala Lumpur had only one relapse in forty-eight Asiatic cases kept under observation from nine to eighty days after a six days' course of atebrin. P. G. E. Jolley⁷ treated eleven cases with atebrin, and observed no relapses during forty days of subsequent observation. A. L. Hoops,⁸ in 253 estate coolies in Malacca, reported only eleven relapses, while David Duncan,⁹ at the Singapore naval base, had eighteen relapses in 168 benign tertian cases treated by atebrin. Barclay Barrowman,⁴ in 805 cases treated by atebrin,

had only thirty-two relapses. From these figures it would appear that the relapse rate in Asiatics treated by atebrin is between 5 and 10 per cent.

48*	F	B.T. & S.T.	27/2/33	9/6/33	0.5	23/7/33	Relapsed
49	F	S.T.	Nil	11/6/33	1.9	Nil	2

* Children.

20. Aged 7 months. Dose 0.5 gram daily.

29. Aged 3½ years. Dose 0.1 gram daily.

35. Aged 8 months. Dose 0.1 gram daily.

48. Aged 10 months. Dose 0.1 gram daily.

It was hoped that results within these limits would be obtained for Europeans, but reference to Table III will show that this is not by any means the case. Out of forty-nine Europeans followed up for from two months to over a year, twelve had a recurrence within one month, three within three months, four within four months, and one, while on a voyage to Europe, within six months of treatment. Assuming that reinfection did not occur in any of these cases, over 43 per cent. relapsed within six months of treatment.

A comparison between the relapse rate in benign tertian and subtertian malaria shows, as would be expected, a higher figure for the former.

TABLE IV.—*Atebrin-treated Europeans*

	B. T.	S. T.	B. T. and S. T.	Total of All Types
Number of cases	28	18	3	49
Relapses	13	5	2	20
No relapse	15	10	1	26
Not traced	0	3	0	3
Relapse per cent.	46.42	33.3	—	43.47

That better results were obtained in treating the primary infection than relapsing cases is shown in Table V.

TABLE V

	First attack	With Previous Recent Attack
Number of cases	31	18
Relapses	11	9
No relapse	17	9
Not traced	3	0
Relapse per cent.	39.28	50

Of cases relapsing after a primary infection, 100 per cent. of subtertian relapses and 57 per cent. of benign tertian relapses occurred within one month of treatment. This is in accordance with the findings for quinine-treated cases, and is best represented diagrammatically.

FIG. 2.—*Atebrin-treated cases*

The total dose of atebtrin usually recommended for adults is 1.5 grams, but in this series of cases it varied between 1.3 and 2.4 grams. To increase the dose above 1.5 grams did not appear to have any effect on the relapse rate. Sixteen adults were given an average total of 1.48 grams, and of these 37.5 per cent. relapsed. Out of twenty-six adults given the larger average total of 1.95 grams 38.4 per cent. relapsed.

Though it is realized that this series of cases forms an inadequate basis for any final conclusions, the difference between a 43 and a 10 per cent. relapse rate invites some explanation. The 5 or 10 per cent. relapse rate of other observers in Malaya is based exclusively, or almost exclusively, on Asiatic cases. The Asiatic, exposed from birth to infection, develops in the course of time an immunity to malaria. This may only be a relative immunity, but it is strong enough to decrease the liability to relapse compared with that of the non-immune

European. A comparison between the immediate effects of treatment by atebtrin on Europeans and Asiatics in Batu Gajah Hospital shows that the average Asiatic responds more rapidly to treatment than the European.

TABLE VI.—*Atebrin-treated Cases. All Types of Malaria*

	Asiatics	Europeans
Number of cases... ..	100	49
Average pyrexial period	38.9 hours	52.5 hours
Average duration of parasites in the blood	42.6 hours	58.6 hours

The difference is more striking when it is realized that the bulk of the Asiatic cases—impoverished Chinese, Indians, and Malays—were undernourished and anaemic, while the Europeans were generally well nourished and in good physical condition.

CONCLUSIONS

1. It would appear that atebtrin is definitely superior to quinine in the treatment of malaria, for it not only reduces the temperature and clears the blood of parasites more rapidly, but is more pleasant to take, and does not give rise to neurotrophic symptoms such as tinnitus and deafness. It is well tolerated by children in relatively large doses, and is invaluable for those showing an idiosyncrasy to quinine. The shortness and simplicity of the treatment is another point in its favour.

2. A high percentage of Europeans develop a yellow discoloration of the skin during or after treatment. This should not be regarded as a sign of toxicity, though it may be a source of annoyance to female patients if it persists for two or three weeks. Atebrin by itself is relatively non-toxic, but it has a cumulative action and is excreted slowly. In consequence, toxic symptoms may not appear until some time after treatment has ended. The signs of toxicity observed in Europeans were headache in one case and abdominal pain in over 12 per cent. of cases. The abdominal symptoms respond very rapidly to treatment by diet and alkalis. Atebrin occasionally appears to have a provocative effect on the parasites of subtertian malaria during the first forty-eight hours; nevertheless it is probably superior to quinine for this type of malaria, and is much less likely to excite vomiting.

3. A combination of atebtrin and plasmoquine is undoubtedly more toxic than atebtrin alone, and for this reason plasmoquine should never be combined with atebtrin in the treatment of the febrile stage of subtertian malaria. It has little or no action on the asexual parasites, and does not appear to influence favourably the tendency to relapses. It should be employed solely as a gametocide after clinical cure has been effected. There is some justification for combining plasmoquine with atebtrin in the treatment of benign tertian malaria, as this combination seems to be more effective in preventing relapses than atebtrin alone, but, owing to the frequency of toxic sequelae, its use should be restricted to those cases under strict observation in hospital.

4. The relapse rate in Europeans after a short course of quinine probably exceeds 60 per cent. Atebrin has reduced this to somewhat over 43 per cent. The relapse rate in Asiatics after atebtrin is probably between 5 and 10 per cent. This is due to an acquired immunity, a statement which is supported by the fact that the Asiatic as a rule responds more rapidly to treatment for malaria than the European. It is doubtful whether prolonging treatment by atebtrin beyond five days lessens the tendency to relapses; 1.5 grams is therefore the optimum dose for an adult. Treatment of the primary attack, particularly in benign tertian malaria, holds out more chance of completely eradicating the parasites than does treatment of a subsequent relapse. In subtertian malaria

—whether treated by a short course of quinine or by atabrin—if a relapse does not occur within two months of the primary attack the prognosis is extremely good. In benign tertian malaria this is not the case; nevertheless, over 57 per cent. of those who relapse after a primary attack do so within two months of treatment.

5. Though atabrin has reduced the liability to relapse in European malaria cases by about 20 per cent., it cannot be said to have fulfilled the somewhat exaggerated claims made for it, but as the precursor of more effective synthetic preparations it is a definite milestone on the road towards the complete eradication of the malaria parasite.

I have to thank the State medical and health officer, Perak, Federated Malay States, for permission to publish this paper, and the patients who, by their intelligent co-operation, have made it possible to follow up the results of treatment.

TREATMENT OF MALARIA WITH ATEBRIN

BY

E. J. R. MacMAHON, L.M.S.S.A. LOND.

TRINIDAD

The following short account of fifty cases of malaria treated with atabrin requires little explanation. A considerably larger number of cases were treated with atabrin and plasmoquine co., but this report deals only with those in which blood films showed parasites before the commencement of treatment. Every case recorded was kept under such observation as is hardly practicable outside institutions; some patients were required to attend thrice daily at the dispensary, and all possible precautions were

taken to ensure that the prescribed courses were carried out punctually and thoroughly. Quinine was administered only in febrile cases, the atabrin treatment being instituted as soon as acute symptoms had subsided. With the exception of yellow pigmentation, which was marked in only one case, any complications arising as the result of treatment were, I am convinced, due to the use of plasmoquine co., and were never of great severity: grave symptoms were noted in two cases (not included in this series, because repeated examinations of the blood failed to discover any parasites), and were attributed to the fact that the patients were not properly nourished whilst taking the treatment.

The mention of "quinine clinic" (Q.C.) refers to the six weeks' treatment which was carried out before the

Case	Age	Sex	Race	Symptoms	Blood	Treatment	Remarks
1	35	M	E.	Malaria. "Rheumatism"	M. T.	15 At./15 P.C.	Acute colic for two hours in middle of course; felt 100 per cent. well at conclusion of treatment. (Colic possibly not due to treatment)
2	40	M	E.	Frequent attacks of fever, resistant to plasmoquine and all forms of quinine. When threatening his continued employment	M. T.	15 At./15 P.C. 7 At./7 P.C.	"Cured" after full course in January, 1933. Later half course precautionary. No recurrence of fever.
3	35	M	E.	T. 103° F. Ague. Frequent attacks	B. T.	Q. to allay fever. 15 At. 7 At./7 P.C. in second week	Felt "cheap" at conclusion of treatment; blood negative. Later half course precautionary. No recurrence since January.
4	20	M	N.	T. 144° F. P. 143. (Q.C. 1931 and 1932)	R. T.	Q. to allay fever. 5 P.C./15 At.	Rapid pulse persisted for eight days after conclusion of treatment.
5	25	M	N.	T. 104.5° F. Ill. (Q.C. 1931 and 1932)	M. T.	Q. gr. 60 in two days. 15 P.C./15 At.	Rapid recovery. No recurrence.
6	30	M	N.	T. 105° F. Prostrated	Mixed (B. and M.)	Q. gr. 80 in two and a half days. 15 P.C./15 At.	Returned to work in seven days.
7	20	M	E.	T. 103° F. P. 128. Otherwise strong	M. T.	Q. gr. 8 four-hourly for two days. 15 P.C./15 At.	Developed yellow pigmentation. No malaria.
9	25	M	N.	T. 103° F. Q.C. October, 1932	M. T.	Q. gr. 20 stat. 15 P.C./15 At.	Off duty for one day only.
11	16 mths	M	N.	Recurring fever. Palpable spleen	B. T.	5 At. half tab. m. et n.	
13	17	M	E.I.	T. 105° F. Weak. (Q.C. April and August, 1932)	M. T. 19/8/33 29/8/33	(1) 10 P.C./10 At. (2) 15 P.C./15 At.	Failed to complete course, so that from August 29th another course was administered. On September 4th blood film showed no parasites. Probably a relapse; possibly reinfection.
15A	17	M	E.I.	Mild fever. Not off duty	M. T. 23/9/33	(3) 15 P.C./15 At.	
17	31	M	E.I.	Chronic malaria. T. 104° F.	M. T.	Q. gr. 20. 15 At./15 P.C.	Blood negative after seven of each tablet.
19	19	M	E.I.	Chronic malaria. Weak	M. T.	12 At./12 P.C. 15 At./15 P.C.	Patient failed to complete full course, so that another course was administered.
22	25	M	E.I.	Chronic malaria. No fever. (Q.C. 1931)	B. T.	2 P.C./15 At.	Blood negative after 2 P.C./7 At.
25	30	M	N.	Four attendances Q.C. 1931 and 1932	M. T.	15 P.C./15 At.	No fever since April, 1933.
30	23	M	E.	T. 103° F. Vomiting	M. T. (crescents)	Int. Q. gr. 7. 15 At./15 P.C.	Colicky pains persisted for several days.
32	14 mths	F	E.I.	Recurring fever. Palpable spleen	B. T.	5 At. half tab. m. et n.	Mild fever on second day of treatment.
35	23	M	E.I.	Chronic malaria	B. T.	15 At.	
38	29	M	N.	Frequent attacks of fever	M. T.	Q. 15 At./15 P.C.	Returned with "fever" two months later. No parasites. Responded to 10d. salicyl. and Q.
39	40	F	N.	Ill. Pains all over. (Q. and P.C. 1931 and 1932)	M. T.	Q. 15 At./15 P.C.	No attack from January–November, 1933.
42	5	F	N.	Frequently recurring fever	B. T. 9/10/33 M. T. 20/11/33	Q. 13 At. 14 At./13 P.C.	Gained 12 lb. in following six weeks.
45	33	M	N.	Frequent attacks. (Three courses Q.C. 1931 and 1932)	B. T.	Q. 2 P.C./15 At.	This patient's blood showed B. T. on October 9th, but treatment was not commenced until November 14th, when M. T. rings were seen. On November 24th a further combined course was administered, the patient taking 27 tab. atabrin in fourteen days without any toxic symptoms.
48	16	M	E.I.	Fever resistant to Q. gr. 10 o.d. for two weeks. Palpable spleen	M. T. (crescents)	16 At./15 P.C.	Blood showing parasites at commencement of treatment, despite two weeks' Q. Fever stopped after 3 At./3 P.C.
50	12	F	N.	Mild fever	Quarant.	17 At./14 P.C. in seven days	No complications.

ABBREVIATIONS.—At. = Atabrin gr. 14.
T. = Temperature.
P. = Pulse.

E. = European.
N. = Negro.
E.I. = East Indian.

Q. = Quinine.
M. T. = Malignant tertian.
B. T. = Benign tertian.

P. C. = Plasmoquine co. (gr. 2 & Q. gr. 1).
Q. C. = Quinine clinic, six weeks' course, with varying doses of P.C.

introduction of the five-day course of atebtrin; patients were usually given twelve tablets of plasmoquine co. during the first week, and two tablets during each of the remaining weeks, the usual quantity of quinine administered daily being twenty grains. Results of this treatment were not to be compared with those obtained from the atebtrin course, as may be gathered from the number of Q.C. references on my list. In my experience the size of a palpable spleen has diminished at about the same rate, whether the malaria has been treated with quinine or by atebtrin. Quinine in large doses (grains xx stat.) brought about relief of symptoms far quicker than did atebtrin in orthodox doses.

The only occasion on which I have injected atebtrin was in the case of an ill-nourished East Indian girl, aged 3, with convulsions. The prognosis seemed hopeless, and I was surprised that she recovered, as my mortality with such cases treated by quinine injections is very high. Case 13 was apparently one of relapse; a careful examination of the surroundings of this patient's dwelling place failed to discover any source of infection.

Each of these patients appeared, and believed himself, to be cured as the result of this treatment; observation over several more months will be necessary to establish the actuality of such "cure." No follow-up treatment has been carried out, except to administer cod-liver oil to a small percentage of these cases: all patients were requested to return immediately to the dispensary in the event of recurrence of fever.

The ages of the patients ranged from under 3 years to over 40, the majority being between 20 and 30 years old. Thirty-seven were males and thirteen females. Europeans numbered six, negroes twenty-nine, and East Indians fifteen. Benign tertian malaria was present in twenty-four cases, malignant tertian in twenty-four, mixed benign and malignant in one, and quartan in one. The course of treatment included: (1) *haustus mag. sulph. & sod. bic.*; (2) quinine with potassium bromide in cases with acute symptoms; (3) fifteen tablets of atebtrin (one t.d.s.) in cases of benign tertian; and (4) fifteen tablets of atebtrin and fifteen of plasmoquine co. (of each, one t.d.s.) in cases of malignant tertian and quartan. At the conclusion of the treatment all bloods were negative, except in Case 42, which had been treated for benign tertian and was found to be a case of malignant tertian (rings) when examined after treatment with atebtrin only. There was only one return case.

CONCLUSIONS

1. That the atebtrin, and atebtrin combined with plasmoquine co., treatment of malaria (in Trinidad) is superior to its predecessors.

2. That atebtrin is an effective preparation which can safely be handed out to patients of moderate intelligence.

3. That the dosage of plasmoquine co. mentioned in this paper is sufficient, and that the advice of the manufacturers—that the administration of plasmoquine be carried out under medical supervision—is of very great importance.

These notes were presented at a meeting of the Southern Division of the Trinidad and Tobago Branch of the British Medical Association, and I am grateful to members for their advice and kindly criticisms, which are responsible for the form of the present report. I am also indebted to the staff of the Apex Oilfields Company for their assistance in securing regular treatment.

The annual report of the Registrar of Births and Deaths, Federated Malay States, draws attention to the fact that throughout 1932 no deaths were recorded from small-pox, cholera, or plague. Eleven deaths were, however, caused by meningococcal meningitis as against six in 1931, and there were forty-six deaths from diphtheria as compared with twenty-nine. It is possible, the report adds, that more exact diagnosis is the explanation of the increased numbers recorded.

THE "RECOVERY PRINCIPLE" IN GAS-OXYGEN ANAESTHESIA

A "CLOSED" SYSTEM

BY

W. B. PRIMROSE, M.B., Ch.B.

SENIOR ANAESTHETIST, GLASGOW ROYAL INFIRMARY

The principle of "gas recovery" as applied to gas-oxygen anaesthesia is a development about which a good deal is being heard at present. Several publications have appeared in journals and other literature under various titles which, however, all deal with the same idea—namely, the use of means whereby general anaesthesia may be maintained by the constant re-use of a limited amount of anaesthetic gas. It may be helpful to define the principle more exactly.

By "recovery principle"—the term to be used throughout—is meant the continuous rebreathing of a relatively small fixed volume of anaesthetic gas which is constantly maintained in a respirable and life-supporting condition. This definition implies a completely "closed" system, consisting of the apparatus and the respiratory organs of the patient with whom the apparatus is connected: it also implies the removal by suitable means of the gaseous waste products of the patient, and the supply to him of an adequate amount of oxygen to sustain life. This idea of recovery of anaesthetic gas is not new, protection by patent having been sought by German and American experimenters from 1926 onwards. Others, in all probability, have had the idea in mind before that, as the chemical basis of the principle has been known for a considerable time. Within the last two or three years British anaesthetists have exhibited an increasing interest in this matter, and have produced experimental machines of remarkable capabilities, but, so far, the possibilities of this method of anaesthesia do not appear to have been sufficiently realized in practice to justify the permanent adoption of the principle by anaesthetists. That the recovery principle has come to stay there can be little doubt, but it has to be developed along lines different from those generally adopted in existing machines.

On looking into the various inventions in this particular field one is struck with the almost complete identity of thought exhibited by the several inventors (including the writer in his earlier experiments). This problem has, in all cases, been approached from an analytical standpoint, which reasons and visualizes the several functions of the necessary apparatus as occurring in a unidirectional cycle, the rhythm of which is governed by the act of respiration. It is therefore found that all recovery machines, described or in use, are constructed according to this point of view, and are therefore very similar in their working and general design. From experience the writer is able to state that this point of view, and the method of construction based upon it, while it works reasonably well, is not the most efficient one, and consequently enough cannot be made of the recovery principle to justify its complete acceptance with confidence. Practical experience with four machines constructed on this scheme of breathing in a circle showed the inherent defects of the method, and it ultimately became apparent that the respiratory circle with its double tubes and directional valves was quite unnecessary. Much better results were later obtained from machines worked by simple to-and-fro breathing through a single tube, since by this arrangement the breath has to pass through the absorbing chamber on *inspiration* as well as on *expiration*. The same, of course, applies to the ether chamber when it is in use. This simple but important change, by thus increasing efficiency, led to greatly improved construction,

and the machine now made according to this arrangement is known as "anaesthetor M 7."

THE APPARATUS DESCRIBED

In this machine the difficulties attendant on the application of the recovery principle have been dealt with rather differently from those occurring with the usual methods described.

FIG. 1.—Diagrammatic section of mouth parts, showing throat tube in position.

Concerning the problem of effecting the closure of the gaseous system (upon which the recovery principle primarily depends) the writer found at the outset that no masking appliance or tracheal tube could do this effectively in all cases. A special tube for introduction into the patient's throat, after the production of unconsciousness by a mask, was designed and tried with success. This tube consists of a very flexible, rustless steel, oval wire coil, over which is drawn a rubber cover that has a small tyre at its free end. This tyre is inflatable from outside the mouth after the tube has been placed in position in the throat. With this breathing tube correctly inserted, and the tyre making close peripheral contact with the pharyngeal wall behind the tongue, the gaseous system is effectively closed. Further advantages are also obtained by the use of this tube. A perfect airway is always provided in any position in which the patient may be placed: no saliva or foreign matter can escape past the tyre into the lower air passages: the head, face, and mouth are accessible for surgical and dental

FIG. 2.—Diagrammatic section of anaesthetor.

work, and positive pressure to individual limits—say, 20 mm. Hg—is easily maintained without leakage. Such pressure is, however, used with discretion. This breathing tube provides the key to the successful application of the recovery principle, and it is an essential element of recovery machines.

The method of absorbing the exhaled CO₂ is also of interest. In the experimental stages the writer was

always encouraged to use granular soda-lime absorbent, but it was found that the dry absorbents were not best suited to anaesthetic conditions—where one had, in many cases, to deal with very low respiratory power. Other objections became evident, such as the difficulty of uniform packing, and consequent irregularity in the track of the breath as shown by the irregular colour change of the absorbent. What was of importance also was the

FIG. 3.—Portable pattern anaesthetor.

difficulty of being able to determine the amount of work that could be expected from a canister that had been previously used. After trial and consideration, the solid absorbents were abandoned in favour of a strong solution of caustic soda. Arrangements were made in the machine to effect absorption of CO₂ at a very low resistance, and also for the handling of such solutions without difficulty

FIG. 4.—Hospital unit anaesthetor.

or danger. This method has proved very successful. The chemical avidity for CO₂ of such a solution is greater than with a solid absorbent; the absorption is uniform, and a simple method has been worked out to give a good idea as to how much absorption any solution is capable of after having been previously used. This is particularly necessary in hospital practice, where the machine may be taken in hand by different anaesthetists.

With these two inherent difficulties dealt with in this way, and construction in accordance with to-and-fro breathing, the machine becomes remarkably simple, light, and compact, with essential parts similar to those of other instruments. In addition, however, there is a level and levelling screws; for it is essential that the machine be level when in use for the proper absorption of the CO_2 . The supply of gases is by simple fine adjustment valves through ordinary sight-feeds. There are no special mixing arrangements required, as the nitrous oxide atmosphere in the machine is absolute, just as is the nitrogen of the air which it replaces. Oxygen is added at the metabolic rate, and delivered almost at the patient's mouth, producing immediate effect.

ADVANTAGES

In practice the "anaesthetor" is simple to work, is most satisfactory from the clinical standpoint, and operates with the highest degree of economy—three gallons or less of anaesthetic gas per individual case, irrespective of duration. Owing to its simplicity of construction, complete dismantling for purposes of cleaning and sterilizing is a matter of only a few minutes' work, and there is no part which cannot be completely sterilized, even to the rubber throat tubes. The rubber of these tubes is of such make that it can be judiciously boiled without damage. Such are the chief advantages that the recovery principle has to offer through "anaesthetor M 7." Space forbids an extended account of its performances, which may be summed up as showing great progress in (1) the management of general anaesthesia; (2) the provision of surgical anaesthetic conditions; (3) the recovery of the patient from the anaesthetic; and (4)—not unimportant—working costs of a previously unheard-of low degree. The apparatus is arranged as a unit suitable for hospital conditions, carrying one 40 cubic foot (or smaller size) cylinder of oxygen and two angle-valved cylinders of nitrous oxide, either 100 or 200 gallon size. The unit is also fitted with "Tyco" blood-pressure-registering equipment. The machine is also arranged as a portable apparatus weighing, with metal case, about twenty-eight pounds. A separate cylinder carrier may be used in conjunction with the machine, and it accommodates very compactly three angle-valve cylinders of any capacity up to the 100 gallon (N_2O) size. Cylinder weight will be reducible in the future when the firms who fill them are in a position to accept the light-weight cylinders unconditionally.

In the tenth annual report of the Ella Sachs Plotz Foundation for the Advancement of Scientific Investigation it is announced that twenty-one grants were made in 1933, one being a continued annual grant. Twelve of the new grants were made to scientists outside the United States, among whom was Dr. H. A. Krebs of Cambridge, who received assistance for the continuation of studies on the breakdown of protein in animals and of the metabolism involved in the action of insulin. Another beneficiary was the Academic Assistance Council of London. In the ten years of its existence the Foundation has made 200 grants, researches being favoured which were directed towards the solution of problems in medicine or surgery, or in branches of science relating thereto. Applications for grants to be held during the year 1934-5 must be forwarded to Dr. J. C. Aub, Collis P. Huntington Memorial Hospital, 695, Huntington Avenue, Boston, Massachusetts, to reach him before the end of April. They must state definitely the qualifications of the investigator, the character of the proposed research, the amount of the grant requested, and the specific way in which the money would be expended. It is advised also that letters of recommendation from the directors of laboratories or clinics where the work is being done should accompany the applications. The maximum size of the grants will usually be less than 500 dollars.

THE MANAGEMENT OF BREAST-FEEDING IN GENERAL PRACTICE*

BY

H. R. YOUNGMAN, M.D. CAMB.

Failure to feed at the breast is still only too common. It will be so as long as this subject is enveloped in the public mind by a cloud of ignorance, evil tradition, and old wives' tales. It is the duty of the general practitioner to lose no opportunity of dispelling this cloud. This paper is limited to the management of breast-feeding in normal cases and slight variations from the normal. Since at least 95 per cent. of cases start normal, it should not be difficult to keep them within these limits.

ANTE-NATAL CARE

It has been stated that a woman's confidence in her natural power to nurse a baby can be inspired "by an exaggerated air of optimism on the part of those about her." Personally I can imagine nothing more calculated to put her off. Rather, the power to give confidence depends on one's gifts of sympathy and tact. But most of all, on one's own confidence that if difficulties do arise one will be able to put them right. The breasts should be examined when the patient is first seen. She should be instructed to brush the nipples with a soft brush and toilet soap daily when washing for the last two months, and to sponge the breasts with cold water before drying them. A warning should be given against any application containing spirit. If there is any retraction of the nipples she should be shown how to draw them out daily and roll them between the finger and thumb with a little oil as lubricant. In extreme retraction it may be necessary to apply a breast pump daily for a time.

PHYSIOLOGY AND ITS APPLICATIONS

The normal stimulus which maintains the secretion of the breast is regular sucking. The response varies with the degree and, up to a point, the frequency of emptying. The normal gain in weight is shown by the dotted curve in Fig. 1. A weight curve on this chart is much more useful than a written record of ages and weights. Every normal child will be found to keep very nearly parallel to this average curve, above or below it according to its weight at birth. A child whose curve does not ascend as steeply as the average for its age is to be regarded as "underweight," and will soon show signs of malnutrition if left alone. The weight at any age taken by itself is no guide to the child's condition. To take an extreme example, in Fig. 1 the child A is normal at ten weeks while the heavier child B is obviously "underweight." In each of these curves it should be noted that the infant gained weight faster than normal for a time after a set-back, tending to regain its former relation to the average. In treating underweight babies one has to aim at this result. For further examples see Fig. 2.

The quantity of milk required for normal progress is indicated in the following table:

Breast-milk Requirements: Normal Infants

Age in Months	Normal Weekly Gain of Weight in Ounces	Milk required Daily per 1 lb. Body Weight in Ounces
0	7	2½
4	5½	2½
8	4	2

Underweight infants require up to half as much again as normal infants of the same weight and age.

* Part of a paper read to the Cambridge Medical Society.

The figure of $2\frac{1}{2}$ ounces per pound is rapidly approached in normal cases during the first two or three weeks, and from a month onwards the figures given are seldom varied from with healthy infants by as much as a quarter of an ounce per pound. Underweight babies, as stated before, are not contented until they are gaining weight faster than normal. Accordingly, during the period of rapid gain they require more food than a normal baby of the same age and weight.

THE FIRST WEEK

As soon as the mother and child have had their first rest, within eight hours of birth, the child should be put to both breasts, for two or three minutes only. It is no use tiring it and giving it wind with sucking empty breasts for long, but the earlier regular stimulation of the breasts begins the better they will respond. If the

FIG. 1.

nipples are retracted, they begin to get drawn out before the breasts become engorged and tender. The child gets the colostrum, and has learned to suck well by the time the milk comes in.

On the first day short feeds like this should be given every six hours, and on the second every three or four hours. Until lactation is established, up to an ounce of warm boiled water should be offered at the end of each feed. As the milk comes in the length of the feeds is gradually increased, remembering what was said above about sucking empty breasts. Both breasts are given at each feed for equal times by the clock, and alternate sides used first. Infants vary in the amount of time they need. A maximum of ten minutes a side should be approached unless signs of over-feeding appear. Babies over seven pounds in weight usually do well on four-hourly feeds. Four-hourly feeds should be given at 6, 10, 2, 6, and 10 o'clock, and three-hourly feeds at 6, 9, 12, 3, 6, and 10 o'clock, leaving in either case an eight-hour night. When lactation is fully established the length of feeds in minutes should be fixed. I am convinced by experience that it makes an enormous difference if one can persuade the nurse or mother to keep rigidly to the prescribed times, not allowing haphazard variations of half, or a quarter, of an hour, and

to time the feeds themselves with a watch. The infant develops a responding rhythm at once. Control of the length of feeds is necessary for the very reason that alterations may have to be made. It is most unsatisfactory to rely on the infant's judgement of when it has had enough, or to trust it to reject any excess. Some do not take enough food for a normal rate of growth unless persuaded; others consistently overload themselves if allowed. In either case the result is a fractious, restless child.

NIGHT TRAINING

For the first few days the evening and morning feeds should be given at exactly 10 and 6, whatever happens. If the child cries at night it must be changed and made comfortable, but on no account should it be lifted up or taken into somebody's bed. A drink of plain water may be given with a spoon. One must, of course, avoid

FIG. 2.

certain things that might make anyone sleep badly. Lack of fresh air and the use of too many bedclothes are common ones.

If there is difficulty after the establishment of lactation, one can shorten the nights temporarily by giving the last feed at 11 or the first at 5, or both, without altering the times of the other feeds. It often happens that a baby that cries in the early morning has to be woken up for its 10 o'clock feed at night, and does not take much because it is sleepy. The remedy is obvious—leave it till it wakes for its last feed. It will be hungry, there will be more milk, and it will have a good meal and sleep later in the morning. One should, however, work back to the proper times. A baby, like anyone else, has a better temper and digestion if it gets eight hours' sleep at night. Under the above regime a few babies sleep all night from birth, and the majority by the end of a week. Some take longer to "settle," but nothing can be gained by allowing them night feeds. When restlessness by night or by day persists into the second week, it is necessary to make sure the child is getting enough milk. Especially is this imperative if it does not begin to regain weight after the usual initial loss. On the other hand, over-feeding is occasionally met with as early as the second week.

OVER-FEEDING AND UNDER-FEEDING

It is very easy to confuse over-feeding and under-feeding. This mistake is constantly being made, with disastrous results, where the obvious diagnostic test of weighing the feeds is neglected. (It appears that infant welfare centres are often managed without any use of test-weighing. This provides the general practitioner with a wonderful opportunity to compete successfully with one of the much-discussed encroachments on private practice.) The following table serves chiefly to show how difficult diagnosis by symptoms may be:

	Over-feeding	Under-feeding
Sleep ...	Usually disturbed	May sleep well if well trained
Crying ...	Caused by colic, and by hunger if much vomiting	Caused by hunger—only towards feeding-time in slight cases
Vomiting ...	Usual	Often present, due to swallowing air when sucking empty breasts
Stools ...	Copious, frequent, often loose, curdy, and green; or constipated if much vomiting	At first constipated, brown; later, small frequent, loose, curdy, and green. "A little whenever changed"
Weight ...	Poor gain or loss. (May be early excessive gain.)	Poor gain or loss

The mother's feelings and the appearance of the breasts are no guide whatever.

In case of doubt, however, the question can be settled for certain by test-weighing. The ideal is to weigh all the feeds for twenty-four hours, but a fair estimate can be made on three, or even two. In estimating, assume the 6 a.m. feed to be $1\frac{1}{2}$ times, and the others not weighed equal to the 12 or 2 o'clock feed. In interpreting results one must remember the increased requirements of under-weight infants.

In most cases of under-feeding there is no need to resort to artificial food. When the test feeds yield three-quarters or more of the theoretical requirements, the supply of natural food can usually be quickly brought up to normal. It may be advisable to change from four-hourly to three-hourly feeds, especially if the child is crying much and, tired out by this, sucking feebly. The other ways of applying extra stimulation to the breasts, which should always be used, are sponging, massage, and expression. Sponging and massage should be done twice a day between feeds; the breasts are sponged with alternate hot and cold water for ten minutes, and then dried and stroked firmly all round from the periphery towards the nipple for another few minutes. After each feed any remaining milk is expressed or withdrawn with a breast pump and given to the child with a spoon. The only things the mother can take which have any effect are good food and more fluid, and extra rest; all the evidence seems to be against so-called galactagogues having any action. In more severe cases of under-feeding it is necessary to complement the breast-feeds with artificial food, temporarily, until the supply of breast milk has been worked up. These cases are outside the scope of this paper.

Over-feeding can often be corrected by simply giving a tablespoonful or two of water before each feed. This should be done first, and then the length of some or all of the day's feeds cut down if necessary.

USE OF BOTH BREASTS AT EACH FEED

Giving only one breast at each feed is the commonest cause of under-feeding and premature weaning. Using both sides at each feed from the start gives a better establishment of lactation, and indeed may lead to over-feeding occasionally. This is much easier to treat than the opposite.

The baby C in Fig. 2 at the age of 9 weeks only weighed two ounces more than at birth, and looked very thin and feeble. The mother said that it slept well and sucked well.

She was feeding it for about twenty-five minutes at one breast, every four hours. It was passing from three to six frothy yellow motions daily, and vomiting a little after feeds—signs of over-feeding at first sight. Test-weighing showed that it was getting about twelve ounces of milk in the twenty-four hours—far below what it needed. I told the mother to feed it at each breast for ten minutes every three hours, and also wrote her a recipe for complementary feeds of modified cow's milk. Three days later she came back and said the baby was "much better, but wouldn't touch the bottles." It never did touch the bottles. So the only change made at X on the chart was from one breast four-hourly to both breasts three-hourly.

Curve D represents a similar, less extreme case. At 13 weeks the mother complained that her milk was not satisfying the baby, that it cried a lot, and had diarrhoea. There were four or five greenish watery motions a day. It was having four-hourly feeds, on one breast each time. It was gaining weight steadily, but only four ounces a week. Test feeds yielded $21\frac{1}{2}$ ounces of milk in twenty-four hours—6 to 8 ounces short of what this underweight baby now needed. The only change made at X was to give both breasts at each feed. The rate of gain was immediately doubled and the symptoms disappeared.

When the first few weeks of breast-feeding have been safely navigated it is much plainer sailing. There must be many more babies unnecessarily weaned in the first and second months than in the third and fourth. I am sure it pays not to part finally from mother or baby until two months after attending a confinement. From the selfish point of view, though the extra attendances may have to be gratuitous in some cases, they bring in a lot of good will. From the professional point of view, the preservation of breast-feeding is first-class preventive medicine, and preventive medicine is the subject in which general practitioners are specialists.

In place of a complete bibliography, which the writer is not competent to give, he would mention the following:

Jewesbury's *Mothercraft*.
Paterson and Forest-Smith's *Modern Methods of Infant Feeding*.
The excellent series of penny pamphlets published by the Mothercraft Training Society, Cromwell House, Highgate, both for distribution to patients and for the edification of the distributor.

Clinical Memoranda

MALARIA IN A EUROPEAN TREATED BY ATEBRIN BY MOUTH AND INTRAMUSCULARLY

In the Third General Report of the Malaria Commission of the League of Nations' stress was laid on the value of atabrin in malignant tertian cases, especially the primary type. The following case may therefore be of interest.

HISTORY OF CASE

On December 27th, 1933, a ship's officer, aged 44, consulted me on account of constant pain in the epigastrium, which proved later to be due to a duodenal ulcer. He stated that he had a slight temperature that morning, but except for the pain, which was severe, did not feel ill. His temperature was found to be 103° , and he was admitted into hospital the same afternoon. A blood smear (thick film) revealed malignant tertian (M.T.) rings, forty to a field, but no crescents. He was given atabrin 0.1 gram t.d.s., by mouth.

On December 28th, 6 a.m., the temperature was 100.6° . The patient's general condition was bad; he was lying on his side hunched up in bed, with flushed and somewhat cyanosed face, foul tongue, weak pulse. He complained of an intense headache at the back of the neck and right side of the occiput. Atabrin was given as before. At 12 a.m. the temperature was 103.4° , remaining up during the day. Urine: albumin, a trace; granular casts.

On December 29th the general condition was as before. At 8 a.m. blood showed thirty-five M.T. rings per field.

and at 10 a.m. the temperature rose to 104.8°. At 11 a.m. atebirin 0.1 gram was injected intramuscularly, and at 4 p.m. there were thirty-three rings per field in the blood. Temperature had dropped to 99.6° at 6 p.m.; and half an hour later atebirin 0.1 gram was given intramuscularly. Atebrin by mouth was taken as before.

On December 30th the patient was better. Tongue was clean and the headache less. At 6 a.m. the temperature was 100.2°; at 8 a.m., eighteen M.T. rings per field; at 2 p.m. the temperature was 102°; and at 6 p.m. 101.8°, when an intramuscular injection of atebirin 0.1 gram was given. Atebrin by mouth was prescribed as before.

On December 31st, at 6 a.m., the temperature was 98.8°. The patient's condition was much improved: headache almost gone; tongue clean. Blood: M.T. rings one in five fields. At 2 p.m. the temperature was 100°, and at 6 p.m. 101.4°. Atebrin by mouth as before; no further intramuscular injection.

On January 2nd the temperature was normal and the blood was clear of parasites. The patient was discharged to ship on January 7th, the temperature having remained normal since January 2nd.

COMMENT

No quinine was prescribed for this patient, who progressed steadily to recovery. The case is of interest owing to the heavy parasitization and the rapid response to atebirin alone, and would indicate the value of resorting to the intramuscular use of atebirin in heavy and dangerous infections with the malignant form of the parasite.

LARGE VESICAL DIVERTICULUM

The following is an interesting case of vesical diverticulum:

The patient, an optician, aged 23, had had difficulty in micturition for the past two years; previously he had been quite healthy. He stated that he could only occasionally pass his water in the upright position, and that he usually found it necessary to lie down or bend over; sometimes the stream would stop suddenly. For the last two months he had suffered from nocturnal incontinence, and had noticed a swelling in the lower abdomen. There was no daily frequency, but he usually woke two or three times in the night with the desire to micturate. There was no history of haematuria.

EXAMINATION

Everything about the patient on January 27th, 1933, appeared normal, except the lower abdomen, where a swelling, thought to be the bladder, was found reaching half-way between the symphysis pubis and the umbilicus, but more marked towards the left side. On the right side a definite swelling could be felt above the pubes. Per rectum a distended swelling could be felt pressing backwards into the rectum.

Cystoscopy.—The capacity of the bladder was twenty-seven ounces. It was much trabeculated, and an orifice of a diverticulum was discovered behind and outside the right ureteric orifice. A diverticulum lamp and the actual cystoscope were passed into the cavity of the diverticulum, but proved of little help, because owing to the large size of the cavity and the fixation of the cystoscope no real view of the interior could be obtained. It was like trying to examine the interior of a large room by standing in the doorway and holding a single candle in front. The cavity was clearly of large dimensions, and such view of the interior wall as could be seen near the orifice showed that there was inflammation of the interior of the sac. The fluid within the cavity was purulent, which also increased the difficulty of getting a satisfactory view. Attempts to wash out the cavity would have had to be prolonged unreasonably, but did serve to show that the diverticulum possessed a definite, though weak, contractile power.

An x-ray examination was made on February 2nd, but nothing was found on the ordinary plate. A ureteric catheter was passed into the diverticulum, which was filled with a solution of sodium iodide, and a cystogram taken. The report stated: "The appearances are not typical of a diverticulum unless it is as large as the bladder."

OPERATION

On February 5th a catheter was passed, and connected by a two-way cock to an irrigating vessel about 5 feet above the level of the patient, who was in the Trendelenburg position. By this means fluid could be run into, or out of, the bladder by the operator, and its distension varied according to the needs of the moment. The usual suprapubic approach to the bladder was made, and the peritoneum pushed upwards, the urachus divided, and the bladder freely mobilized. The bladder was found to be enlarged, and when opened at a later stage of the operation to be at least half an inch in thickness, owing to hypertrophy of the muscle. It was pushed forward and somewhat to the left by the diverticulum, which was at least as large as the bladder, lay behind it, and overlapped it on the right side, and practically occupied the whole of the pelvis.

The diverticulum, therefore, was the swelling which had been felt just above the right side of the pubes. The separation of the peritoneum from the back of the sac was difficult, tedious, and took a long time, but once the lower reflexion was reached the rest of the separation was relatively easy. When the diverticulum was delivered into the wound the right ureter was observed running from behind forwards below its neck. The ureter was carefully stripped away from the vicinity of the diverticular neck, which was then completely isolated. The external diameter of the neck was found to measure about an inch and a half, and its substance contained dense fibrous tissue. During the final stage of the operation the bladder was opened by a mid-line incision, and the final separation and division of the neck guided by the help of a finger inserted from the bladder through the orifice into the cavity of the diverticulum. When the diverticulum was removed the internal orifice, previously seen by the cystoscope, was found to measure about half an inch in diameter. The hole in the bladder was sutured and the incision into the anterior wall completely closed. Rubber dam drainage was inserted down to the site of the orifice of the diverticulum and into the prevesical space. The wound was then closed in the usual manner, a catheter being tied into the urethra.

AFTER-HISTORY

The patient had a mild pyrexia for a few days, probably due to a post-operative bronchitis. On February 21st the catheter was removed, but owing to the appearance of a slight suprapubic leakage it was reinserted next day. It was finally removed on March 8th, when the wound was dry and healed.

Specimen.—Immediately after the operation the specimen was distended with water from the tap, but, in order to avoid damage, only a certain amount of water was introduced. This was measured and found to be just over ten ounces. The specimen was then carefully stuffed with wool to prevent contraction, but in spite of this there was some diminution in size before it was finally mounted. The interior of the cavity was observed to be inflamed, being dark red and velvety in appearance. Before final mounting a window was cut in the wall, and the piece removed used for a microscopical section. The section shows no trace of mucous membrane, considerable fibrous tissue, and degenerating muscle fibres.

Cystoscopy in the out-patient department on March 30th showed that the interior of the bladder was slightly inflamed and highly trabeculated. The site of the diverticulum has practically disappeared, and its situation is now ill defined. The patient is in excellent health, and passes his water easily and naturally, though there is still a slight frequency.

Reviews

RHEUMATISM IN GENERAL PRACTICE

Once more a medical man has applied himself to the task of compiling a work on the complex subject of rheumatism¹ which shall be intelligible to the general practitioner, and, on the whole, Dr. M. B. RAY is to be congratulated on his achievement. In a foreword, Lord Horder gives it as his opinion that this is the best book on rheumatism in the English language. Perhaps that is not such high praise as it sounds, for neither in this nor any other language has the entirely satisfactory book on rheumatic disease yet been written.

Dr. Ray starts with a preliminary chapter on the physiology of the skin and heat regulation, and goes on to consider diathesis and the powers of adaptation of the body to various environmental conditions. Acute and subacute rheumatism and rheumatism of children is then dealt with. We doubt if the idea of including Still's disease in this section is a happy one, for it is now generally held that Still's disease is essentially a manifestation of rheumatoid arthritis in young subjects, and that the splenic and lymphatic involvement is a peculiarity of the age of the subject and not of the disease process. The chapter on fibrositis is a good one, and gives a competent picture of the protean manifestations of this reaction; the discussion of "neuritis" is admirable, and the importance of differentiating between a perineuritis and a parenchymatous neuritis is adequately stressed.

"Metastatic" arthritis is discussed in two chapters: one devoted to those cases associated with specific infections, such as gonorrhoea, tuberculosis, or dysentery, and one with focal infection, such as apical abscess, infected tonsils, gall-bladder, etc. Dr. Ray favours the separation of rheumatoid arthritis as a clinical entity, and with this view most of those who have had long experience of rheumatic diseases will concur. He regards this syndrome as fundamentally different from his metastatic group, and seems to imply that their differentiation is therefore easy; with this contention few will agree. Reliance is placed on the radiological appearance of the hand in diagnosis, and photographs are reproduced, but few people, unless they are very expert in interpretation, would feel confident in making a diagnosis from an examination of such plates. It is possible that in the future this may prove to be a real assistance in diagnosis, but it cannot be claimed so far that it has a wide application. Gout is discussed between rheumatoid arthritis and osteoarthritis, which would seem to be an unfortunate position, for gout is surely a disease *sui generis* in which joint affection is incidental. It is perhaps logical to include serum sickness, toxic arthritis, and so-called rheumatic purpura in the same chapter, as they are all probably allergic conditions. Osteoarthritis is then discussed, and Dr. Ray includes "Heberden's nodes" in this category, though most people would associate these with fibrositis rather than with osteoarthritis, especially as it is uncommon for patients exhibiting these nodes on the fingers to suffer from osteoarthritis in other joints. Neurotrophic arthritis is included here, and Dr. Ray considers that something more is involved in such cases than an arthritis in an insensitive joint, but he is by no means clear as to what that something is. No mention is made of a form of "climacteric" arthritis in which endocrine disturbances are prominent, though this is not uncommonly differentiated in treatises on rheumatic diseases. The final chapter of the first part gives a useful summary of the various measures of physical treatment applicable in rheumatic diseases. The second part of the book treats

of rheumatic infections considered regionally, and from the point of view of differential diagnosis is admirable. Probably it would have been better to restrict this section entirely to this, for the notes on treatment are redundant and out of place. There seems to be no reason, for example, to treat cervical fibrositis differently from fibrositis of equal intensity in any other region, and a perusal of this section does not disclose any special method not advocated elsewhere.

The book is written in a readable style, but it is a little disappointing, in view of Dr. Ray's long and varied clinical experience, that he does not give us more of his own opinion. He is very erudite and quotes many opinions, but sometimes leaves us in the air, wishing to know what he thinks. For example, is osteoarthritis primarily a degenerative disease, or is infection a prime factor in its causation? Both views are quoted, but Dr. Ray is unwilling to commit himself. The reader may consider that the author has lived long enough in the south to have outgrown the caution acquired in his earlier northern habitat and tell us what he really believes. The arrangement of the text is admirable, and the paragraphing and clear headings make reference easy. References to authors are given in the text, which is perhaps a pity, and not all of them are accurate. So far as this notice is critical it is because the reviewer regards this book as worth criticizing and, *a fortiori*, worth reading. In view of the very wide incidence of rheumatic disease and the large proportion it assumes in the daily work of every practitioner, all medical men will be well advised not only to read but to possess this volume, in which the subject is presented in such a way that information bearing on the needs or complaints of any patient is easily obtained, and a practical solution of most difficulties of diagnosis and treatment is offered.

PULMONARY TUBERCULOSIS IN INFANCY AND CHILDHOOD

ARMAND-DELILLE and LESTOCQUOY's luxurious "atlas,"² recently published, should go a long way towards remedying the state of confusion which exists on certain aspects of pulmonary tuberculosis in childhood. The book is a combined clinical, radiological, and pathological study of nearly a thousand children who have been under their care at the Hôpital Hérodin in Paris. Moreover, it should be added that, as secretaries of the Oeuvre Graucher, the authors have had the opportunity of observing the large number of home contacts recommended and accepted for boarding out in the country.

The first part of the book is devoted to their methods of investigation. These have already been the subject of a note in the *Journal* on March 3rd (p. 370). Special stress is laid on lateral skiagrams, and, in case of death, the fixation of thoracic organs by a method which permits accurate comparison of anatomical sections with x-ray photographs. Finding it essential to arrange their material in some logical sequence, the authors discuss and reject both Aschoff's histological and Ranke's three-stage classifications (the latter not very convincingly), and adopt the classical two-stage French theory of "primo-infection" and endogenous reinfection. In both sections they deal in turn with the various macroscopic pathological entities encountered, each lavishly illustrated with well-reproduced skiagrams (mostly full-size), with excellent photographs of morbid specimens and their histological sections, and with clear two-colour explanatory diagrams. Finally,

² *La Tuberculose Pulmonaire et les Maladies de l'Appareil Respiratoire de l'Enfant et de l'Adolescent (Iconographie de l'Hôpital Hérodin)*. Par P. F. Armand-Delille et Ch. Lestocquoy, avec la collaboration de René Huguenin. Introduction du Professeur Calmette. Paris: Amédée Legrand 1933. (Pp. xu + 500; 352 figures, 212 explanatory diagrams. In one volume, 350 fr.; in two volumes, 375 fr.)

¹ *Rheumatism in General Practice*. By M. B. Ray, D.S.O., M.D. London: H. K. Lewis and Co., Ltd. 1934. (Pp. viii + 404; 6 plates. 16s. net.)

there are chapters on treatment (artificial pneumothorax and other methods of collapse therapy) and on general diseases of the respiratory system.

A few points of great interest brought out in Armand-Deille and Lestocquoy's work may be mentioned. They indicate the frequency of various types of lesions at different ages. Certain false conceptions based on radiological evidence only are clearly demonstrated: for example, that a perihilar x-ray shadow does not correspond to "perihilar tuberculosis," the existence of which they doubt; that basal tuberculosis is rare, the x-ray shadow often seen in the right base being due to infiltration of the middle lobe; and that x-ray infraclavicular infiltrations really belong to the "apex" of the lung. A good deal of space is given to an account of "epituberculosis" or "spléno-pneumonie": the latter term, first coined by Grancher and descriptive of the morbid appearance presented, is retained by the authors. They consider that it represents 50 per cent. of the pulmonary tuberculosis in children between 5 and 10 years old, and bring forward a certain amount of evidence to show that it is an extensive oedematous or cellular alveolar infiltration in which characteristic tuberculous lesions or tubercle bacilli can seldom be demonstrated. Often (but not necessarily) this infiltration is in the vicinity of a partially or completely healed tuberculous focus. There is here a close correspondence with the phenomenon of hypersensitivity in the skin when a positive tuberculin test is obtained.

It is much to be regretted that full references are omitted from a text which repeatedly mentions the work of other authors. Whatever views the reader may have with regard to the aetiology and mechanisms of tuberculosis in childhood (and he might well be disposed to criticize Calmette's statements in the Introduction in particular), the book forms a "living document" on which he can base his own opinions.

VETERINARY HYGIENE

The second edition of *Veterinary Hygiene*,² by R. G. LINTON, Ph.D., M.R.C.V.S., professor of that subject in the Royal (Dick) Veterinary College at Edinburgh, is a most satisfactory book of reference for the modern veterinary practitioner, the student, and the official. In all statistical respects it is an excellent piece of work, which reflects the greatest credit for industry and accuracy upon the author and his collaborators, whose names are given in the preface. If the reader wishes to build a stable, a byre, or kennels, to construct a dipping bath for cattle and sheep, to analyse the air or water supply, as well as to know every detail of the orthodox procedure for the control of infectious diseases of animals required by all kinds of official regulations, he will find what he needs in this book. But if he wishes to know more of prophylaxis from a pastoral point of view, he must go elsewhere, because not much space is given to this vital aspect of the science of health. It is to be regretted that Professor Linton has not chosen to say more on this topic at a time when, as the result of the economic decay of farming in Britain, diseases of animals, due largely to a deteriorated environment, are by no means decreasing, and at a time when dairy cows, owing to the ravages of tuberculosis, mastitis, infectious abortion, and Johne's disease, are said to have an average productive life of less than four years.

There is an apparent discrepancy in this book which may be of general interest. In discussing sewage-polluted water the author alludes to an experiment carried out at the Research Institute of the Veterinary College in London during 1932 and 1933, in which three cows were

given large quantities of diluted crude sewage for twenty-one months and thrived on it. This evidence was probably the deciding factor in an important legal case which was settled in the Court of Appeal last year. If it is to be an accepted fact that human and other organic sewage is innocuous to cattle—and Professor Linton does not dissent—the thirty-nine pages of his chapter on water would appear to have mainly an academic interest so far as veterinary surgeons are concerned. On the other hand, a subject of great practical importance to a considerable number of veterinarians—the sea and land transport of animals—is not mentioned in this edition.

THE "ANNALS OF EUGENICS"

In the recently issued Parts III and IV of volume v of the *Annals of Eugenics*¹ the papers of most direct interest to the medical reader are by Dr. Ethel M. Elderton and by Dr. Percy Stocks and Miss M. N. Karn. The report issued by the Department of Health for Scotland on the Lanarkshire experiment was subjected to some criticism on the ground that the experiment had not been planned in a way calculated to measure satisfactorily the relative advantages of raw and pasteurized milk. Thus, *inter alia*, raw and pasteurized milk were never given in the same schools, and the initial heights and weights of controls and milk-fed children were not the same. Dr. Elderton has attempted to evaluate the importance of the second criticism by sorting the cards into age and sex groups, and then forming pairs of children of approximately equal initial heights and weights. Having done this, she has compared the respective gains in heights and weights. Her general result is that girls derived more advantage than boys from the milk ration, and, on the particularly controverted question, she finds that "there is no evidence that raw milk has an advantage over pasteurized or pasteurized over raw in increasing growth when the two are directly compared on this selected material." Professor Pearson, dealing with the same issue, points out that there seems to be some difference between the sexes, in that in girls raw milk did seem to promote growth in stature more than pasteurized milk.

Dr. Stocks and Miss Karn provide a very detailed comparison of samples of patients suffering or not suffering from cancer. The plan adopted was the following. Each observer was asked to record elaborate particulars of a hospital patient suffering from cancer and to choose another hospital patient within five years of the age of the former but not suffering from cancer. The same information was recorded with respect to the control as noted for the cancer patient. In the end, 462 schedules of cancer patients and 435 of controls were obtained. The investigators then had to answer a whole series of questions of the following kind: an article of food, for instance, white bread, is (a) never eaten, (b) occasionally eaten, (c) eaten weekly, (d) eaten daily by such and such proportions of the cancer patients and the "control" patients. Are the differences between the proportions in the two series such that it is improbable that they can fairly be regarded as samples from a common population? The result of applying the test is to show that in many of the characters studied there is no significant differentiation. There are, however, exceptions. It seems clear, for instance, that the use of certain vegetables was less frequent in the cancer than in the control series. The authors are careful to point out that no suggestion is made by them that all or any of the vegetables yielding these results prevent cancer, that they go no further than to

² *Veterinary Hygiene*. By R. G. Linton. Second edition. Edinburgh Veterinary Series. Edinburgh: W. Green and Sons, Ltd. 1934 (Pp. 472; 129 figures. 21s. net.)

¹ *Annals of Eugenics*. Vol. v. Parts III and IV. October, 1933. Edited by Karl Pearson and E. M. Elderton. London: Francis & Taylor Laboratory for National Eugenics, University of London. (Pp. 227-415; illustrated. Annual subscription, 50s. net; double parts, 35s. net.)

suggest that more research should be undertaken. The same remark applies to other discrepancies found.

With this issue Professor Karl Pearson relinquishes editorial control of the *Annals*. "My endeavour," he writes, "during the twenty-two years in which I have held the post of Galton Professor has been to prove in the first place that eugenics can be developed as an academic study, and in the second place to make the conclusions drawn from that study a ground for social propaganda only when there are sound scientific reasons upon which to base our judgements, and, as a result, our opinions as to moral conduct. Even at the present day there are far too many 'general impressions' drawn from limited or too often wrongly interpreted experience, and far too many inadequately demonstrated and too lightly accepted theories for any nation to proceed hastily with unlimited eugenic legislation. This statement, however, must never be taken as an excuse for indefinitely suspending all eugenic teaching, and every form of communal action in matters of sex." Few men have served the cause of truth with so single-minded a devotion as the author of those words. Professor Pearson has lived to see the kind of ill-balanced "publicist" who, a generation ago, sneered at eugenic "fads," eagerly demanding, in at least one country, drastic legislation. He was never discouraged by opposition, he is not elated by praise. His successor enters upon an intellectual inheritance worthy of the traditions of British science.

BIOCHEMISTRY FOR MEDICAL STUDENTS

We have much pleasure in welcoming the fourth edition of Mr. T. R. PARSONS'S *Fundamentals of Biochemistry*^a in relation to human physiology. This work was written with the purpose of providing medical students with a short and readable account of the chemical changes that occur in the human body. During the decade that has elapsed since it first appeared there has been a very great growth in the subject of biochemistry, but the author has succeeded in preserving his original aim—namely, that of presenting an outline of the more fundamental biochemical topics in the form of a story rather than of a catalogue. The book covers a very wide range of knowledge, but the author has kept it within reasonable limits of size. He has a remarkable gift for presenting the essential facts in a form that is brief and yet both readable and accurate. The chapter on vitamins is an example of this; for in fifteen pages an account is given of the salient facts regarding the biochemistry of vitamins, an account which includes such recent advances in knowledge as the formulae of carotene, vitamin A, and ascorbic acid. In general, the book can be recommended to all who wish for a simple and yet accurate account of the principles of biochemistry which are of chief importance in the study of human physiology.

Notes on Books

The first number of the new volume of the *Annals of Medical History*^b opens with Dr. JOSEPH WALSH'S pleasantly written account of Galen's works and the influences which made him so extremely active; the pen is said to have, with two periods of abstinence, been constantly in his hand from the age of 13 to 68. This article pays a tribute to Professor Johannes Ilberg (1860-1930) of Leipzig, to whose researches the world is indebted for most of its accurate chronological knowledge

about Galen's life. Dr. A. C. Krause of Baltimore, in an article on Assyro-Babylonian ophthalmology, points out that Herodotus's description of the extremely primitive character of Assyro-Babylonian medicine is, as a result of the recent interpretations of the cuneiform texts, erroneous, and that in point of fact there was an elaborate medical organization, and that before 2000 B.C. surgeons performed operations on the eyes. Dr. E. C. Jessup of Long Island writes with a bibliophilic enthusiasm on incunabula: of the two or three hundred thousand in existence, out of the estimated twenty millions printed, there are perhaps twenty thousand medical; he specially deals with the earliest medical item—namely, *De Sermonum Proprietate, seu de Universo*, 1467, which was an encyclopaedia with a chapter on medicine and diseases. The astonishing fact is that it was written by Rabanus Maurus, Archbishop of Mainz and one of the foremost scholars of the age of Charlemagne, who died in 856, and that the text was therefore already six hundred years old when it was first printed. The other three articles in this instalment of the *Annals* deal with the eighteenth century: Drs. Leona Baumgartner and Elizabeth M. Ramsey conclude their study of that wonderfully modern hygienist Johann Peter Frank; Drs. W. T. Dawson and J. Chapman write on withering and digitalis; and, in his extremely interesting essay on medicine in Horace Walpole's letters, Dr. Robert Hutchison draws a contrast between the letter writer, who had not any friends in the medical profession, which he ran down, and Samuel Johnson, his contemporary.

Mr. MACLEOD YEARSLEY'S attractive little book on *Doctors in Elizabethan Drama*,^c as he announces in the introduction, forms part of a hitherto unpublished work on the medicine of Shakespeare and his contemporaries, of which it is to be hoped subsequent portions will appear in due course. Including the introduction the present volume contains six chapters, devoted respectively to the consideration of medical education and practice in the Elizabethan era; physicians as dramatis personae, of whom no fewer than forty-nine occur in Shakespeare and his contemporaries, though only eighteen are given names; surgeons and apothecaries, of whom the former occupied a decidedly inferior position to the physicians, while the latter often incur a good deal of abuse and ridicule owing to their frequent trade in poisons; midwives and nurses, the latter including the monthly nurse, the wet nurse, the children's nurse, and the sick nurse; and irregular practitioners who, in the form of montebanks, quacks, bone-setters, and astrologers, were extremely rife in the Elizabethan period. Mr. Yearsley is to be congratulated on the meticulous care with which he has searched the texts not only of Shakespeare but of his contemporaries, including Beaumont and Fletcher, Ben Jonson, Chapman, Dekker, Ford, Greene, Heywood, Massinger, Middleton, and Webster, for appropriate passages to illustrate his text.

Chemical and Microscopical Examinations at the Bedside,^d by H. LENHARTZ, seems to be a popular textbook on clinical pathology as practised in Germany. The eleventh edition, published this year, is a book of about 370 pages, and well illustrated.

Medical Notes and First-Aid Treatment for Flights in the Tropics and Sub-tropics (H.M. Stationery Office, 4d. net) is intended for the personnel of the Royal Air Force when engaged in flying in localities where medical aid is not available. It is not concerned with medical aeronautics, as a casual glance at the title might suggest, but deals in a very elementary fashion with the commoner tropical maladies and their prevention. The text is simply and clearly written, and the first-aid notes on drugs and their employment appear to be fool-proof. The manual should prove very useful to those for whom it has been compiled.

BRITISH POST-GRADUATE MEDICAL SCHOOL

HISTORY AND RECENT PROGRESS

Certain recent announcements may justify a review of the circumstances which gave rise to the institution of the British Post-Graduate School at Hammersmith.

London has long been realized to have a remarkable, indeed almost unique, supply of clinical material. Of this advantage should be taken not only in the training of medical students by undergraduate schools but, in addition, by the provision of courses for doctors resident in this country, in the Empire beyond the seas, and abroad who wish to refresh their knowledge, to obtain instruction in new developments of medicine, surgery, and obstetrics, or to participate directly in the clinical practice of a hospital.

Attempts to utilize this abundant material are by no means new. In the closing years of the last century the Medical Graduates College and Polyclinic was set up largely through the activities of Sir Jonathan Hutchinson. This organization was of great value to London practitioners, but was not run in connexion with any one particular hospital, and, although there were associated with it classes in certain special hospitals and medical schools, it could not provide that regular attendance at in- and out-patient departments which may be looked on as the principal requirement of the general practitioner and the more specialized post-graduate student.

With the next stage of the development should be remembered the name of Sir William Osler. Among others, many of whom are fortunately still with us, he made possible the formation of the Fellowship of Medicine and Post-Graduate Medical Association. During the years which have since elapsed many practitioners have been thereby enabled to take advantage of the instruction provided at the various London teaching hospitals. This organization is still very active and does most valuable work, and there has been no falling off either in the facilities which it offers or in the numbers who have taken advantage of those facilities. Nevertheless, the Fellowship of Medicine suffers, in some measure, from not having any one hospital with which it is particularly associated, and thus it has no really adequate centre for its activities.

THE ATHLONE COMMITTEE

To trace the story of the School back to its inception, in January, 1921, the then Minister of Health (Dr. Christopher Addison) set up, at the suggestion of the University Grants Committee, a committee, under the chairmanship of the Earl of Athlone, to consider provision in London to meet the needs of medical practitioners and other graduates. Chief among the recommendations which it made in its report, published in May, 1921, were the following: (a) There should be a school, attached to a hospital in London, which should be devoted solely to post-graduate instruction in clinical medicine, including surgery, midwifery, etc., and (b) an institute should be established in which instruction should be given in public health, etc. While the committee paid full tribute to the services rendered by the Fellowship of Medicine and Post-Graduate Medical Association, particularly in the first matter, it concluded that higher medical education in London was still, and unwarrantably, behind that provided in Continental centres such as Vienna. It was the second of these recommendations that came first to fruition.

In July, 1926, Mr. Neville Chamberlain, the then Minister of Health, laid the foundation stone of the London School of Hygiene and Tropical Medicine, whose development had largely been made possible by the very generous grant of the Rockefeller Foundation towards the cost of appropriate new buildings. In July, 1929, the School buildings in Bloomsbury were opened by His Royal Highness the Prince of Wales. However, the other objective of the Athlone Committee remained to be secured. Its report unfortunately appeared at a time when post-war depression had already begun, and in consequence the project was born out of season.

A PRACTICABLE SCHEME

As soon as it was possible Mr. Neville Chamberlain set up a new committee with a membership which included representatives of the Royal Colleges of Physicians and of Surgeons, of London University, of the great teaching hospitals, and also of the British Medical Association, and of the Fellowship of Medicine. The terms of reference of this committee were more specific: "To draw up a practicable scheme of post-graduate medical education centred in London."

This committee's report constituted a substantial advance in several respects. After a careful survey of the existing teaching institutions it concluded that it was financially impossible to set up an entirely new hospital and medical school, and also that it was impracticable, for many and different reasons, to associate the new school with any existing teaching hospital. However, the position had been again altered by the passing of the Local Government Act in March, 1929. Under its provisions there came under the control of the London County Council between twenty and thirty public general hospitals and, therein included, about 17,000 beds. The committee then investigated the advisability of associating the new post-graduate medical school with one of these establishments.

At the hospital in Ducane Road, Hammersmith, there were about 400 beds, in a building no part of which was more than 25 years old. Even before the question of a post-graduate school had arisen in this connexion, the L.C.C. had described the hospital as "exceptionally good and well designed for the purposes of a hospital dealing with the acutely sick." With the full co-operation of the L.C.C. the committee made further and more detailed inquiries, and finally came to the unanimous conclusion that the conversion of this (the Hammersmith) hospital was the best solution of the problem.

THE FIRST STEPS

In April, 1930, Mr. Arthur Greenwood, the then Minister of Health, announced in the House of Commons the Government's acceptance of the recommendations of the committee and its willingness to contribute a sum up to £250,000 for building and equipping the school. Furthermore, it would provide, through the University of London, annual grants for the maintenance of the school. This decision was followed by the setting up of a committee, over which Lord Chelmsford presided, and, as a result of its recommendations, a Royal Charter was, on July 10th, 1931, granted to the School. The Charter appointed a governing body and entrusted to it the supervision of the erection and equipment of the School and its management when it came into existence.

Soon after came the financial crisis of 1931 to put the whole scheme in jeopardy. After very necessary and serious consideration the Government of the day decided that it would be against the public interest if the scheme were to be indefinitely postponed, and that, in spite of the difficult state of the national finances, it would invite Parliament to make a grant not exceeding £100,000. The L.C.C. agreed to expend a similar sum on such developments and adaptations of the existing hospital as were found to be most desirable at the present time in view of its forthcoming association with the School.

For financial reasons the commencement of the building had to be delayed; but on July 17th, 1933, the foundation stone was laid by Mr. Neville Chamberlain. The building work is being carried out by the L.C.C. under the terms of an agreement with the Governing Body.

The L.C.C. is, on the hospital side, providing new buildings for midwifery cases, for out-patients, and for casualty departments as well as many other modifications, while the School buildings will consist mainly of laboratories, lecture theatres, and accommodation (non-residential) for the teachers and students.

"LAY-OUT" OF THE BUILDINGS

Though very substantial progress has been made during the last seven months, there is as yet but little to show the ultimate arrangement of the buildings in hand, and a brief description of the general "lay-out" may be appreciated. Though some parts are more specially addi-

tions to the existing L.C.C. hospital and others particularly concerned with the new School,—they have been designed to serve the best interests of both institutions, and must in large measure be considered as a whole.

The present buildings are set at right angles to a corridor running through east to west, along which beds can easily be wheeled and cases moved from one ward to another. It is at the eastern end of this corridor that the chief new building is being erected. The medical school part of the block stands back further from Ducane Road and has three stories arranged round a square courtyard, thus providing abundant light and ventilation.

On the ground floor there are the Medical School offices, including accommodation for the dean, for clerical staff, etc., and a committee room. These take up one side of the square, while the north side is chiefly occupied by the post-mortem department, with an associated laboratory and classroom for histological work. Opening off the main corridor mentioned above is the clinical theatre (with accommodation for close on 100 students) and rooms for the examination of patients and for the lecturers. The remaining side is chiefly devoted to a large chemical laboratory with centrifuge, polarimeter, and balance rooms.

The second floor can be described more briefly: above the clinical theatre is a somewhat larger lecture theatre (both of these include full provision for the projection of cinematograph films), while over the School offices are to be found a well-lit library and two rooms for the use of the teaching staff. The remainder of the floor is devoted chiefly to five medium-sized laboratories and six smaller rooms, each of the latter suitable for a single worker. There is, in addition, a large museum with windows on two sides and top lighting as well. The top, or third, story is slightly smaller; it contains bacteriological laboratories, autoclave rooms, and two smaller laboratories. To turn now to the southern half of this new block—a part which belongs more closely to the hospital—on the ground floor the L.C.C. is providing a large and carefully planned out-patient department. The main hall is lit from above, and will accommodate about 300, while opening off it are various consultation and examination rooms and a theatre for minor operations. Adjacent to the general out-patient hall, but with a separate entrance, is the ante-natal care department, while also on the ground level are two small wards available for casualties. Though provision has been made for later expansion upwards as occasion arises, there are for the present to be only two stories in this part of the building. The upper floor is chiefly devoted to an x-ray department, on the one side to investigative work—for example, screening and photography—and on the other to therapy. It is believed to be the intention of the L.C.C. to send from its other hospitals to Hammersmith any patients who might be expected to benefit by the facilities there provided for specialized treatment or investigation and diagnosis.

The out-patient department is not the only substantial addition to the hospital; there is also being erected a new block chiefly for maternity cases and well provided with delivery rooms, operating theatres, etc.

TEACHING ARRANGEMENTS AND POLICY

It was announced the other day that London University had "recognized" the new institution as a school of that University, and also that it had approved certain proposals with regard to the conditions of tenure, etc., of the professors. There is little doubt that in a few weeks at the most the members of the Governing Body will find themselves able to complete the necessary preliminaries, and to proceed to the steps necessary to fill the various chairs. As mentioned in a note appearing at page 490, there will be four professorships, three in the main clinical subjects—medicine, surgery, and midwifery and gynaecology—and the fourth in pathology. The former group will, by arrangement with the London County Council, have general charge of the beds in the hospital which are devoted to their various subjects, and will also be provided with facilities for original investigations in medical science. The "research" accommodation will, of course, be supplemental to the laboratories required no less than lecture rooms for the teaching of the post-

graduate student. The department of pathology will require rather more generous laboratory accommodation and equipment, but this subject now includes at least three main divisions: (1) morbid anatomy, (2) biochemistry, including pathological chemistry, and (3) bacteriology.

When it has been possible to select the holders of the chairs—and these posts have already been advertised in the medical press—the next stage will be to proceed to the more detailed organization of each teaching "team," for we must presume that assistants of various grades will be needed in each unit. No doubt, courses will also be delivered from time to time by eminent physicians and surgeons not permanently attached to the school.

It is of the first importance that the teaching should be of a really high level—suitable for increasing the knowledge of the better grade of medical practitioners. The provision of "refresher courses" may well be regarded as an important item in the activities of the comprehensive post-graduate scheme. Such courses should be particularly adapted to the needs of men who are working in sparsely populated rural areas, and who have not reasonable access to a town in which hospital practice is available. Nevertheless, this type of activity should not be allowed any chance of "swamping" the more advanced work, which may be expected to appeal more particularly to graduates proposing to specialize in some one branch of medical practice. For these, courses of an essentially different character will be needed.

"THE CENTRE OF A GREAT TEACHING ORGANIZATION"

It is not to be expected, nor, indeed, is it desirable, that the whole of post-graduate teaching in London should be transferred to Hammersmith. Such a plan would overlook the abundant clinical material and teaching ability which are to be found in the existing special and general hospitals, and which have, chiefly through the activities of the Fellowship of Medicine, been made largely available, for example, to medical graduates from over-seas. Rather is it to be hoped that the new School will act as a centre and that a cordial relationship will be maintained with other institutions and their valuable and generous work. To quote the report of the Athlone Committee in 1921: "In order to meet the needs of (1) practitioners able to devote up to three months to general instruction, (2) those seeking further knowledge in special subjects, (3) officers in the Services on study leave, and (4) graduates from over-seas, a post-graduate medical school should be instituted which should be attached to a large and well-equipped hospital, and should be the centre of a great teaching organization in which the London special hospitals, the Poor Law infirmaries, and the existing medical schools with their clinical units and research departments would all find their place." Nevertheless, it should be emphasized that though the School is being set up in London, and though it will of course be most readily accessible to practitioners resident in the capital, its appeal must not be restricted in any way. The School, with its close and novel association with a public hospital owned by the L.C.C., has a national side in that it represents the beginning of an organized attempt to enable general practitioners to keep abreast with the advance of medical knowledge—and a progressive and up-to-date corps of general practitioners is the foundation of any sound scheme for public health. The School has an Imperial side, since nowhere more keenly than in the great Dominions is the desire felt that it should be possible for medical men to find in London and among their own folk access to the latest knowledge and the most recent developments of medical technique. It also may claim to have a distinctly international side, since in countries like the United States of America and the Argentine (to mention only two) the desire for such an institution in London is constantly expressed. Great advantage can be expected to accrue to the School, and to the advance of medicine, by the presence of a certain number of colleagues and fellow students from countries whose system of medical training differs somewhat from our own.

The early stages of the School's work must be, to a great extent, provisional, and on the experience then gained future courses will have to be designed.

SATURDAY, MARCH 17th, 1934

CEREBRAL STRUCTURE AND FUNCTION

It has been estimated that there are some twelve thousand million (12×10^9) nerve cells in the human brain. A wealth of anatomical interconnexion endows the mechanism with a complexity which can stagger the imagination, even of those who are accustomed to astronomical dimensions. Nevertheless, the grouping of a few pathways, such as the visual tracts and those leaving the motor area of the cerebral cortex, has allowed inferences to be made as to their general categories of function. The effects of destruction of portions of the brain by disease or by experimental lesion permit the labelling of particular areas with various general functions such as visual perception. The most elaborate cartography of the cerebral cortex according to its cellular pattern, and the careful study of the change of such patterns by disease, has thrown a little light on the relation between structure and function. Compared with the known complexity of structure the sum total of knowledge of the actual details of function of any part of the brain is profoundly meagre. The many advances in biochemistry, in histology and histopathology, in electrophysical methods, and all the other tools at the call of the modern investigator leave untouched a problem which has exercised the contemplation of all philosophers. The behaviour of the mind gives no indication of the way in which nerve energy is transformed into mental energy.

Sir Charles Sherrington, in the fulness of years of patient and fruitful research into the fundamental processes of nervous activity, sets before us a delightful essay on the physiological mechanism of the brain.¹ The subject-matter forms the Rede Lecture, delivered in Cambridge last December. The complexity of the most lowly of the spinal reflexes involves complete accounts of the subject in a bewildering glossary of technical terms, but here in everyday language and with entertaining lightness of touch the great problem of cerebral nervous function is stated. In simple language the issues emerge the more clearly. For essential principle in any consideration of cerebral function it has long been customary to regard the brain as an elaboration of elementary reflex circuits. There is, in fact, a dearth of competing hypotheses. In the nervous network of these circuits the hypothetical wearing of pathways can be made to accommodate the various aspects of the subconscious mind, of conditioning, or of memory. The utility of fundamental theory on this basis is severely restricted by lack of

¹ *The Brain and its Mechanism*. By Sir Charles Sherrington, F.R.S. London: Cambridge University Press. (1s. 6d. net.)

any information as to the way any one part of the cerebral nervous mechanism functions. The spinal reflexes exhibit the effects of interaction of the two nervous states, excitation and inhibition, arising as a result of stimulation. It appears reasonable to suppose that the cerebral neurones are subject to the same phenomena, but here the source and control of these states offer a baffling problem. Inhibition is an active state, and requires to be maintained by nervous activity. If, for instance, sleep be considered as the effect of inhibition then sleep must be an actively maintained process.

In this lecture Sir Charles Sherrington brings forward no fresh elaboration of hypotheses, but critically examines the old, to throw the poverty of verified scientific fact into clear relief and to etch the problem the more clearly. Indeed, he pauses to consider whether solution will ever be found, as might a hardened mountain climber reflect on the possibilities of reaching the topmost peak of Everest.

D'ARSONVAL AND HIS WORK

"I am convinced that therapeutics of the future will employ as curative methods physical agents such as heat, light, electricity, and others still undiscovered. The rude system which, under pretext of curing, merely poisons with the most potent drugs known to chemistry, ought to give way to physical methods whose use has at least the advantage of introducing no foreign substance into the body." So said d'Arsonval in 1881, in the days before the discovery of x rays or radium. Now in 1934 it has become difficult even to imagine the limitations upon treatment which would ensue in medicine and surgery were physical methods suddenly withdrawn from our reach. In the medical treatment of certain forms of rheumatism, vasomotor disturbances, poliomyelitis and pneumonia, and in gynaecology—most conspicuously in the cure of cervical erosion—diathermy has been proved to have valuable effects unobtainable by any other known treatment. The enormous progress in surgery of the urinary tract can be attributed directly to development in the use of high-frequency currents for fulguration and electrocoagulation. The happy results in the treatment of common disfigurements are another instance of the successful application of such currents, used with skill and fine control. Yet these are only a few developments of the work of one man, Arsène d'Arsonval, in whose honour the Sorbonne celebrated a jubilee last May in the presence of a most distinguished and enthusiastic assembly. To Professor d'Arsonval, then in his eighty-third year, homage was paid for the great benefits to mankind which are the outcome of his research and discoveries, and he was acknowledged in many eloquent addresses as the father of modern physiotherapy.

The October issue of the *Journal de Radiologie et d'Electrologie* appeared as a special jubilee number containing reports of the Sorbonne speeches, interesting

articles on d'Arsonval's life and work, and facsimiles of two noteworthy letters. Of these, one is Professor d'Arsonval's own charming letter of thanks to the *Journal* for honouring his work, for so long unrecognized and misunderstood, and the other the letter from Claude Bernard, which obtained from d'Arsonval's father permission for his son to devote himself to a scientific career instead of becoming an assistant in his practice at Limoges. Arsène d'Arsonval had commenced the study of medicine reluctantly, not from his own choice, but in compliance with his father's wishes and the family tradition. Medicine did not interest him, for he felt it was too empirical and inexact to satisfy his mind, which was of a clear, scientific quality, more suited to the study of mathematics or physics. But a chance meeting with Claude Bernard at the Collège de France suddenly proved the inspiration which transformed his career into a passionate study of the relation of physics to the phenomena of life. Claude Bernard, the foremost physiologist of the day, saw in the young d'Arsonval that rare combination of qualities which distinguishes the mind of a great man, and by welcoming him in his own laboratory continued to inspire him and provided the milieu for his researches.

So well known is d'Arsonval's name in connexion with his discovery of the therapeutic uses of high-frequency currents that his work in other subjects, immense and varied though it was, is apt to be overlooked. In a short space it is impossible to give an account of the many problems that his fertile brain investigated, or of the success of his efforts in different undertakings. He invented many delicate instruments for use in laboratory experiments, and his remarkable "calorimètre-à-compensation" was the origin of all modern calorimetric methods. Earlier workers on the physiology of muscle had been content in their experiments with records of gross visible contractions, but d'Arsonval went further than this, devising his myophone, which was able to record the minimal contractions, imperceptible by other means. From this he evolved his theory of the importance of the form of electric wave used, "la caractéristique de l'excitation," which was the basis for later experiments. While using high-frequency currents, he observed that the stimuli they excited diminished as the frequency was raised, and he expected that by further increasing the frequency a state might be reached at which no stimulation would occur. At that time (1889) no means were available for producing a frequency higher than 10,000 per second; but by a most fortunate coincidence Hertz then discovered how to produce a current with a frequency of several millions, and d'Arsonval was able to test his theory and found it correct. In 1891 he communicated his findings to the Société de Biologie, shortly before Tesla, in New York, reached the same conclusions. With this tremendous advance d'Arsonval applied himself more ardently than ever to his research on high-frequency currents, designing his own apparatus and experimenting on himself. Through his study of

electrical burns and the phenomena of electrocution, he advocated the treatment of electric shock by artificial respiration, which has meant the saving of many lives. At first his ideas and discoveries were rejected with scorn, but happily he has lived to see them accepted and increasingly employed.

When the first attempt at wireless telegraphy was made from the Eiffel Tower, apparatus designed by d'Arsonval and Oudin ten years before was used, and provided the impetus for the rapid development of broadcasting. In another field commercial firms owe to d'Arsonval the discovery of the methods of sterilizing organic fluids by cold, which have made possible the manufacture of the products used in organotherapy. It ought to be more widely known that d'Arsonval, in collaboration with Brown-Séquard, played an important part in investigating the properties of organic liquids, and foresaw the development of endocrinology, of which he said, in 1891, before the Société de Biologie: "We believe now that all tissues, whether glandular or not, contribute something to the blood, that each phase of nutrition is accompanied by internal secretion. We believe consequently that all the tissues can and ought to be used in special cases as a mode of treatment; that, in a word, a new therapy will be created in which the medicaments will be products made by different tissues of the body. . . ." Whatever subject d'Arsonval touched, he enriched it by the originality of his ideas, and the debt medicine owes him is incalculable. But with the modesty and simplicity characteristic of a great man he attributes his success to the circumstances in which destiny placed him—his meeting with Claude Bernard, his niche in the laboratory of the Collège de France, the affection of his wife and the solace of his home, and his own insatiable interest in the phenomena of life. In addition to his great achievements as a scientist, d'Arsonval is a serene philosopher, whose kindness of heart and equable temperament endear him to all who have the good fortune to be his colleagues.

BRITISH POST-GRADUATE MEDICAL SCHOOL: WHOLE-TIME CHAIRS

In our advertisement pages last week there appeared a notice by the Senate of the University of London inviting applications for four university chairs tenable at the British Post-Graduate Medical School at Hammer-smith, which is expected to open its doors next autumn. These professorships are in medicine, in surgery, and in obstetrics and gynaecology, each with a salary of £2,500 a year, and in pathology, at £2,000. Applications (twelve copies) must be received not later than first post on May 4th by the Academic Registrar, University of London, S.W.7, from whom further particulars may be obtained. We have before us the full announcement relating to the chair of surgery, from which the terms of the other three may be inferred. Candidates must possess qualifications which are registrable in Great Britain, and their applications must be accompanied by the names of not more than three

persons to whom reference may be made. If any of the referees are resident abroad they should be asked to write direct to the academic registrar without further intimation. Under the University regulations the board of advisers is not limited in its choice to persons who have applied for the post. The full title of the holder of the chair will be "professor of surgery in the University of London and director of the surgical unit at the British Post-Graduate Hospital and Medical School;" and the professor will be appointed by the London County Council to the office of surgeon to the Post-Graduate Hospital. The chair will be a whole-time appointment and the professor may not hold any other public appointment, nor engage in any other professional work without the approval of the Governing Body of the School. He may not hold office after September 30th in the session in which he attains the age of 60, subject to a proviso that the Senate, on the advice of the Governing Body, can renew the appointment until a later age as provided by the regulations on university titles. Subject to the directions of the Governing Body, the professor will have charge of the surgical unit at the hospital and direct and supervise the work of the students in that unit. He will be required to organize a department of clinical research and to do all in his power to promote and advance the study of surgery. Other conditions as to tenure, superannuation, and duties are set out in the official announcement obtainable from the academic registrar. An article, describing the inception of the School and the progress so far made with the scheme, appears at page 487.

ABDOMINAL MANIFESTATIONS IN RHEUMATISM

Under this title in 1931 Dr. K. H. Tallerman contributed an article to these columns¹ which drew attention to the possibility of involvement of one of the serous membranes of the body—the peritoneum—in the course of rheumatic infection. In a special number of the *American Journal of Pathology*,² in honour of Frank Burr Mallory, Dr. L. J. Rhea has recently discussed the occurrence of rheumatic peritonitis. He bases his remarks on the case of a man of 25 who had suffered from three previous attacks of acute rheumatic fever, in which the heart had become involved. He was admitted in his last illness with abdominal cramps and aching pains in front of the chest, radiating to the back. His abdomen was found to be rounded, a little distended, and with resistant abdominal muscles. With rest in bed and proper medication most of the signs and symptoms partly or wholly disappeared. Then heart failure supervened, and during the last few days of illness the patient complained of generalized abdominal pain. At necropsy the peritoneum showed evidence of localized areas of acute inflammation, and, microscopically, except for the fact that the lesions were diffuse, the appearances were similar in every way to the so-called Aschoff bodies found in the heart in this and in other cases of rheumatic fever. Dr. Rhea believes that such lesions are specific, resulting from the action upon the peritoneum of the causative agent of the disease. He suggests that involvement of the peritoneum in rheumatic fever is more common than is generally thought. This is borne out by the reports³

of other cases in France, showing, however, points of difference. Two of these were observed by M. G. Baudet, who reported a similar case in 1931. In one, that of a girl of 18, the illness began with a typical acute appendicitis, which was dealt with by operation. Fifteen days later one of her wrists became painful, red, and swollen. This was resistant, however, to sodium salicylate, so the rheumatic nature of the abdominal disorder must be reckoned doubtful. The other case was in a man of 21, who complained of pain in the right iliac fossa after cavalry exercises. Operation revealed a congested appendix and in the abdomen a certain amount of clear fluid, which was sterile on bacteriological examination. Some days later the knees became painful and swollen, and there was much general perspiration. Treatment with sodium salicylate removed all the articular signs and symptoms within forty-eight hours. At the same discussion in France, M. Robert Monod described another variety of abdominal rheumatism. A woman of 32 began her illness with an acute follicular tonsillitis, followed about twelve days later by a localized painful swelling in the thyroid gland. After twenty-four hours this had settled down, but suddenly, a week later, acute pain in the right iliac fossa supervened, with vomiting. Some rigidity of the abdominal muscles developed slowly, and three days later a very slight degree of congestion in the appendicular and caecal regions was observed at operation. The appendix was removed. Five days after this diffuse articular pains recurred, with some swelling and redness of the metatarso-phalangeal joint of the left foot. There was also fever, and it was thought that a mitral systolic murmur could be heard. Sodium salicylate quickly relieved all signs and symptoms. This last case does appear to be one of rheumatic appendicitis, with some degree of peritoneal reaction, but in all three of these French cases the diagnosis is retrograde, since arthritis appeared after the abdominal manifestations. Diagnosis before this stage would have been impossible, and exploration of the abdomen was inevitable in all three. The preceding tonsillitis in the last patient is of especial interest.

TOXIC GASES

It is perhaps too late in the development of modern civilization to express horror and disgust at the amount of intensive research still being carried out on war gases. Nor does it serve to deter nations to remind them that nearly twenty years of study of the technique of gas warfare have elapsed since the "black day of Ypres," when the first great gas attack was made by the Germans. In a recent work by O. Muntz, one of the principal medical officers of the Reichsheer, pride is taken of the fact that "it remained to German scientific genius, as so often before, to bring gas warfare to an effective military form." These twenty years have made gas warfare, as it was known in 1915-18, seem childish, but simultaneously methods have been devised to combat gas attacks, and with man's extraordinary power of adaptation it is possible to say, as Dautrebande does in *Les Gaz Toxiques*: "It is not to be considered that these war gases constitute a particularly deadly or mysterious arm. It also appears to us useless to

¹ *British Medical Journal*, 1931, ii, 844.

² 1933, vol. ix, Supplement, p. 719.

³ *Bull. et Mém. Soc. Nat. de Chir.*, 1934, ix, 5.

⁴ *Les Gaz Toxiques*. Par L. Dautrebande. Paris: Masson et Cie. (60 fr.)

protest violently against their use." This author goes on to argue that gas warfare has not that particularly inhuman character which one was inclined to give it in the first days. In the last war gas casualties numbered less than 9 per cent. of those from other methods: also, while of English casualties only 3.3 per cent. of the gassed died, other methods had a mortality rate of 25 per cent. Further, while the civil population has no special means of defence against the usual arms of war, it has a very effective special defence against gas attack, so that Dautrebande considers gas as the least murderous of war methods. It seems to us that this is going too far, for antidotal methods are known only for the gases whose compositions have been published, and we have no means of knowing what deadly compounds are in the hands of possible enemies and which would find us, in case of war, without effective measures. War has a habit of bringing surprises. But this monograph offers much matter of extreme interest, and describes in detail the properties of a great variety of substances which can give rise to toxic results, whether they fulfil the criteria of a war gas or not. Very abundant detail is given in the consideration of the physiopathology of the respiratory tract, and much will be found to interest the clinician and physiologist. An excellent chapter on the carotid sinus is particularly to be recommended.

THE DYEING OF EYELASHES

Last year the *Journal of the American Medical Association*¹ published reports of seven cases of eye injuries, several of them severe, following the use (in all but one instance) of a preparation known as "lash lure" and said to contain an aniline derivative. Three of these patients had keratitis and uveitis, three others had recurring attacks of dermatitis and conjunctivitis, while in the seventh there were dense corneal opacities leaving permanently obstructed vision. Whether the damage was due to personal idiosyncrasy or to an excessively strong solution or to careless application does not seem to be clear. The Health Commissioner of New York took a serious view of the situation, and in a communication issued on November 23rd he announced a ban upon the manufacture, sale, or use, in beauty parlours in the city, of dyes known to contain harmful ingredients. Several examples of dyes charged with causing eye afflictions showed a high presence of aniline derivatives, while two others were found to contain such large percentages of silver nitrate as to render them dangerous. The ban does not extend to the use of eyebrow pencils or "mascara," or, presumably, to the familiar lamp-black preparations which need repeated application to the eyelashes and (being merely superficial "paints" and not dyes in the true sense) are proof against neither tears nor rain. It is generally agreed that while all hair dyes are to some extent dangerous, the descending order of potential harmfulness is: (1) aniline ("para" and its associates); (2) mineral dyes (copper, silver, and lead, generally combined with pyrogallol or sodium thio-sulphate); (3) vegetable dyes such as henna. "Lash lure" appears to belong to the paraphenylenediamine group, and as such would be likely to produce a severe reaction in sensitive persons.

¹ *Journ. Amer. Med. Assoc.*, July 29th and November 11th, 1933.

Eyelash dyeing in the strict sense, by which is meant the use of some chemical substance that blackens the whole hair shaft and causes it to retain its colour, enjoys a certain popularity in this country. Many of the smallest hairdressers, at any rate in London and the big towns, will undertake to dye a customer's eyelashes for a very small sum. The higher grades of beauty specialists ("beauticians" in America) may have as many as 300 regular customers on their books who pay visits at two-monthly intervals when the naturally growing and untinted eyelash has become (to them) unpleasantly conspicuous. In most cases, however, hairdressers are not anxious to dye eyelashes and are careful to warn the customer of possible dangers. Some sort of medical history is generally taken, and a few firms employ a skin test. This is seldom the patch test recommended by Ingram,¹ but usually involves applying the dye powder dry on the skin, which has been lightly scarified beforehand. It is of interest here to note that even with the patch test there may be a greatly delayed reaction, and Ingram recommends that the patient should be under observation for at least a month. As to the actual application of an aniline dye, hydrogen peroxide is used to make a paste; this is put on with orange sticks to the lashes of the closed eye, and generally takes ten to twenty minutes to act. It is then removed. The mechanism aimed at is the oxidation of the dye in the hair shaft, the resultant substance in the case of "para" being the relatively inert "Bandrowski's base." Ingram estimates the idiosyncrasy to the phenylamine diamines at 4 per cent. among normal persons. If this figure is accepted it is surprising that the practice of eyelash dyeing has not been followed in England by consequences as disastrous as those reported in America. It may well be that manufacturers have succeeded in obtaining a substitute for "para" which is less irritating than one has reason to suspect; it may be that no dye as strong as "lash lure" is used, and it may be that the technique of application and selection of "cases" receives more careful attention over here.

METCHNIKOFF'S LAST PAPERS

At the time of Metchnikoff's death two of his writings of considerable interest—namely, *The Death of the Silkworm Moth* and *The Sexual Function*—remained unpublished. These articles are supplementary to his *Studies on Human Nature and Optimistic Essays*, and on that account, as well as from their inherent interest, it has been deemed advisable to publish them. They are now included, together with his work on Pasteur, Lister, and Koch (published in Russia in 1915), in a volume entitled *Three Founders of Modern Medicine*.² In the two articles mentioned, Metchnikoff returns to the subject of longevity and normal death or thanatology, to use his own expression. He quotes the Italian Bodio to show that the average duration of life is no greater now than it was in the time of King David, if the first years of infancy are left out of account. He enumerates many circumstances which conspire to limit the duration of life to the present average of seventy.

¹ Ingram, J. P.: *Brit. Journ. Derm. and Syph.*, 1932, xlv, 424.

² *Trois Fondateurs de la Médecine Moderne*. Par E. Metchnikoff. Nouvelle collection scientifique. Paris: Félix Alcan. (15 fr.)

years, which cannot be accepted as the normal duration. He himself attached great importance to the intestinal flora, which he regarded as injurious, in opposition to the general opinion that there is symbiosis between the microbes and the human organism. He believed that by suitable dietetic measures, adopted from infancy onwards, the intestinal microbes could be eliminated, and that this, together with the prevention of disease through the increase of medical and hygienic knowledge, would lead to the prolongation of life to its normal length, terminating in normal death. Here Metchnikoff assumes the role of philosopher, propounding his doctrine of orthobiosis, that the end of existence is life itself, active, conformed to the disposition of the individual and prolonged to the onset of the instinct of death, when man experiences the satisfaction of having lived long enough and begins to desire death, to which he voluntarily yields. One must be content at present with the average duration of life, but normal death may be made the subject of scientific investigation. Metchnikoff sought a suitable subject for experimental research, and found it in the silkworm moth. This creature is incapable of taking nourishment; it is not organized to live more than a few days (about fourteen), and, as death occurs before the nutritive reserves in its body are exhausted and independently of injurious physical conditions such as desiccation, its death may be regarded as normal. Metchnikoff made an exhaustive histological study of the tissues, but could find nothing to throw any light on the cause of death; then, turning to the secretions, he made the interesting discovery that after the first few days the moth exhibited complete retention of urine, and the fluid taken from the enormously distended cloaca was found to be highly toxic. He concluded that "although the moths react to pain to the last moment, one must believe that they die poisoned by the products of their own organism, without suffering and without the apprehension of death. One may hope," he adds, "that this end, which the moths reach by a simple natural process, will be attained in the future by men also." Apparently he considered the toxic substance to be the product of a special internal secretion.

SECTION OF RADIOLOGY AT BOURNEMOUTH

At the Annual Meeting of the British Medical Association next summer the Section of Radiology and Electro-Therapy will meet on July 25th, 26th, and 27th. Unfortunately these three sessions coincide with the International Congress of Radiology at Zürich. The officers of the Section appreciate that there will be great difficulty in obtaining speakers, especially as it will be impossible to have any foreign guests, and because so many British radiologists will be going to Zürich. At the same time, they are very anxious to make the Section a success, and are arranging what they hope will be an attractive programme. The honorary secretaries (Dr. G. Lieba Buckley, 29, Poole Road, Bournemouth, and Dr. John Roth, 40, Harley Street, London, W.1) would therefore be glad to hear of any radiologists or electrotherapists (members of the Association) who intend to visit Bournemouth for the Meeting, especially those who would be willing to take part in the discussions.

THE PHARMACOPOEIA COMMISSION

The *British Pharmacopoeia* which was published in September, 1932, has been on the whole favourably received, but has necessarily led to considerable criticism of detail. The new Pharmacopoeia Commission, which took office in October, 1933, is now engaged in dealing with these criticisms, in investigating disputed points, and in collecting the material required for revision. Expert subcommittees have been formed to deal with different aspects of the work. It is proposed that a complete revision shall be made during the next seven years, and that a new *Pharmacopoeia* shall be issued in 1941. It is proposed, also, to publish an addendum in 1936. This will contain any alterations in the standards and tests of the *Pharmacopoeia* which experience shall have shown to be advisable, and will include descriptions of, and standards for, new drugs. The Commission is desirous of the opportunity of considering comments upon the standards and tests for the substances included in the *Pharmacopoeia*, and it invites manufacturers, pharmacists, and others to send to the secretary of the Pharmacopoeia Commission, 44, Hallam Street, W.1, any representations they wish to make.

LORD ABERDEEN

The Marquess of Aberdeen, who died on March 7th, was elected an honorary member of the British Medical Association in 1897, during his period of office as Governor-General of Canada, which coincided with the Annual Meeting of the Association at Montreal in that year. The Marchioness was elected an honorary member in 1909, on the occasion of the Belfast Meeting, during Lord Aberdeen's Lord Lieutenancy of Ireland. At the memorial service held in London on March 12th at St. Columba's, Pont Street, the British Medical Association was represented by its Treasurer, Mr. N. Bishop Harman.

The twenty-fourth Oxford Ophthalmological Congress will be held in Keble College from July 4th to 7th. On the morning of July 5th a symposium on functional diseases of the eye will be opened by Sir Farquhar Buzzard from the neurological, Mr. Williamson-Noble from the ophthalmological, and Dr. William Brown from the psychological, aspect. The Doyne Memorial Lecture will be given by Professor Joseph Meller (Vienna) on "Tuberculosis and its Relation to Spontaneous, Post-traumatic, and Sympathetic Ophthalmia."

According to the quarterly return of the Registrar-General, the birth rate in England and Wales for the last quarter of 1933 was 12.8 per 1,000 population—the lowest ever recorded. The birth rate for the whole of 1933 is provisionally estimated at 14.4 per 1,000; the death rate at 12.3 per 1,000 population; and the mortality of infants under 1 year at 64 per 1,000 live births.

The ninety-eighth annual general meeting of the Royal Medical Benevolent Fund will be held at 11, Chandos Street, W., on Thursday, March 22nd, at 5 p.m., with the president, Sir Thomas Barlow, in the chair.

THE HASTINGS LECTURE

The sixth Sir Charles Hastings Popular Lecture, arranged by the British Medical Association, was given in the Great Hall of the Association's House, Tavistock Square, on March 7th, by Dr. Robert Hutchison, whose subject was "The Food of the Growing Child." The attendance was almost a record in the history of these lectures, and every seat on the floor of the hall was occupied. Lord Horder took the chair, and among others on the platform were the Mayor of St. Pancras (Mr. F. Hewson), the Chairman of Council of the Association (Sir Henry Brackenbury), the Treasurer (Mr. Bishop Harman), Dr. C. O. Hawthorne, Dr. F. W. Goodbody, Dr. Alfred Cox, and the Medical Secretary (Dr. G. C. Anderson).

LORD HORDER briefly introduced Dr. Hutchison, and reminded the gathering that these lectures were primarily intended to form a liaison between the medical profession and the public interested in personal and public health.

Dr. HUTCHISON then delivered his lecture (which was printed in full in last week's *Journal*, p. 439).^{*} The lecture occupied just an hour in delivery, and Dr. Hutchison managed to bring to an important subject not only a good deal of common-sense counsel, but more than a few touches of dry humour.

QUESTIONS AND ANSWERS

At the close, members of the audience were invited to send up questions, and for twenty minutes Dr. Hutchison was occupied in answering, very tersely, a sheaf of them. The first question was whether tobacco smoking adversely affected the growth of the adolescent. Dr. Hutchison replied that there was no scientific reason to suppose that tobacco smoking did so, but smoking between meals undoubtedly interfered with appetite, and therefore indirectly might interfere with growth. Asked why sugar was more harmful than starch if taken in excess, especially in view of the fact that starch was absorbed into the blood in the form of sugar, he said that the reason was that starch took some time in conversion, its absorption was very slow, and the blood was not flooded with a large amount of it at once. Again, sugar was an irritant in strong solutions. Grocers working with sugar got eruptions on the arm, called grocer's eczema, and in the same way there was irritation of the stomach if excessive quantities of sugar were taken, a thing which did not happen with starch. Another questioner asked whether fruit did not help to avoid constipation, which was one cause of lack of appetite. Dr. Hutchison replied that that was a very roundabout way of getting the result. Raw fruit was not nearly so laxative as many people supposed. A pill might be at least equally effective, and it did not "fill one out" as fruit did. Asked whether he advised cereal foods for the child's breakfast, he said that as a Scotsman he still stuck by porridge, but the objection to cereal foods in general was that from the nutrient point of view they were not worth their cost. They were a costly way of buying starch. There was no physiological objection to them, but there was that economic one. In reply to a question as to how to produce an appetite in a child, he said that this often meant big changes in the child's surroundings, one of the first being, perhaps, to send the child away from his mother.

^{*} *Corrigendum*.—In Dr. Hutchison's Lecture, as printed in the *Journal* of March 10th, the second sentence of the first paragraph should read: "and it is right that his name should be kept in remembrance, for in founding the Association he conferred a great benefit not only on the medical profession," etc. Owing to a printer's error the fifth line was omitted and line 10 of the same paragraph reduplicated.

These "appetist" children were nearly all solitary children, and on that account received too much notice. If taken away from the company of adults and made to sit down at meals with children of their own age they often did better. Asked how to deal with inability to take fats, he said that it was a matter of proceeding cautiously, beginning with small quantities, seeing that the fat was distributed through various foods, and using milk, which was probably the fat most easily taken. But there were some children whose livers never learned to deal with fat, so that they could not enjoy fats in anything like the average amount. On the question as to the desirability of milk, he said that, however good it might be, a great many children could not digest it. If it was a rule to give every child a pint or a pint and a half of milk a day, there would be a large minority unable to digest it comfortably. Asked what quantity of milk a child 2 years old should require he replied, "a pint."

Another questioner wanted to know how to tell when a child's appetite was normal, and whether it did not vary with the individual. Dr. Hutchison replied that that was just the point. The child's appetite was an index of the demand at the moment for energy intake. Each person dealing with a particular child knew the range of that child's appetite. As an outside observer he could only say of a child that he was a hearty eater or that he had an extremely bad appetite; the many intermediate stages could only be estimated by those who were with the child constantly. Asked as to the differences in the amount and kind of food required in summer and in winter, Dr. Hutchison said that during summer most children stood still or lost weight. Weight was chiefly gained from late September until the end of March. Appetite tended to fall off in the hot season, though the energy demand might be at the same level. If the child was forced to take part in active exercises in the summer he might readily lose weight. Asked whether he advocated forcing children to eat when they had no appetite, he said that he doubted whether this could be done. The best way of dealing with children with no appetite was to take no notice of them; not to coax or persuade them. They would eat less than ever in order to get attention. In the desire to receive notice they would eat very little at meals, and the more they were coaxed and persuaded the more definite was their resistance. Asked in what way brain-work affected food requirement, Dr. Hutchison said that educational overstrain did interfere with the power of digestion. The child who was worried and overstrained, as, for example, at examinations, suffered in his digestive power and hence his power of taking in and making use of adequate quantities of food, the result being loss of weight. Some question was raised as to the diets of different nationalities, but Dr. Hutchison remarked that such comparisons were extremely difficult. The differences between a Swede and an Englishman, for example, could not be explained on diet alone, but took in racial, climatic, and habit factors. In reply to a question as to the cause of acidosis, he said that it was usually due to the intake of more fat than the child could deal with relatively to his digestive capacity—not necessarily to an excess of fat in the diet. Asked whether conditions of the mouth, such as carious teeth and septic tonsils, were not a cause of loss of appetite, the lecturer replied that he did not know, but they might set up some catarrh of the stomach. He insisted, in reply to another question, on regular meal-times, with no extras between meals to tempt the child with a poor appetite. "Those who will not when they may, when they will they shall have nay." He approved, however, of the giving of milk to school children between meals: a glass of milk in the middle of the morning was all to

the good. One member of the audience urged a curfew for children, on the ground that insufficient sleep was a cause of lack of appetite. Dr. Hutchison agreed, but thought it would meet with opposition from the children and their mothers.

VOTES OF THANKS

Dr. C. O. HAWTHORNE, in proposing a vote of thanks to the lecturer, said that the Popular Lecture had been associated with a reasonable degree of entertainment and inspiration. Perhaps Dr. Hutchison's professional colleagues would particularly appreciate the lecture as illustrating the truth, which was not always recognized, that the practice of medicine was common-sense, associated with and founded upon technical knowledge, and that the object of medicine was not merely the cure of certain patients, but the prevention of disease and establishment of health. The lay audience might well be particularly grateful to Dr. Hutchison for having dealt with a highly technical subject in so lucid a fashion and with a minimum supply of polysyllables. There were two points on which he wished to congratulate him: first, the success and distinction with which he had passed his "examination" (meaning the facility with which he had answered the questions put to him), and secondly, the large contribution of service which he made

to his profession as a physician, and, that evening, as a lecturer.

Dr. HURCHISON said that it had been a great pleasure to come and address the gathering, and an additional pleasure to have a vote of thanks proposed by a fellow countryman of his own, because he knew that Scotsmen were not given to flattery. He felt complimented, too, on seeing that so many had taken the trouble to come and listen to him, but he did not know whether it was altogether a good sign of the times. He could not help feeling that this interest in food was a little morbid, and that his audience might have been better employed in amusing themselves in some other way and have left the growing child to nature!

LORD HORDER, in reply to a vote of thanks which was moved by Dr. Hutchison, said that he had not hesitated for a moment when he received the invitation to preside, and nothing could have given him greater pleasure than to be associated on the platform with Dr. Robert Hutchison. Dr. Hutchison had brought to bear upon his theme a happy combination of extensive experience and practice with children, and of researches which throughout the whole of his professional life he had been carrying on in matters of diet. This had enabled him to present the subject not only happily and lucidly, but "with authority and not as the scribes."

France

[FROM OUR CORRESPONDENT IN PARIS]

Length of the Medical Curriculum in Paris

While various devoted reformers have been cudgelling their brains over the reform of the medical curriculum and the addition of another year of studies, it is natural to ask what is the burden, counted in time, under which the medical student already labours. A recent study¹ by the secretariat of the Faculty of Medicine of Paris deals with the 596 medical students who qualified as doctors in 1933. It was found that 85.73 per cent. had taken six years or more to qualify. There were only two who had been industrious and nimble-witted enough to satisfy their examiners in as short a time as five years and two or three months. There were seventy-nine who had taken exactly six academic years, and 430 who had exceeded this limit—by how much we are not told.

A General Medical Council for France

The Bill providing for a new "Order," with functions similar to those of the General Medical Council in England, has now been passed by the Chamber of Deputies. Introducing it to the Senate on January 25th, Dr. Gadaud reviewed its antecedents. In the past schools of medicine had vouched for scientific attainments by examinations and diplomas, but had not taken moral probity into account. Hitherto, traditions of honour and the high standing of medicine in France had assured moral as well as scientific probity. To-day, the conditions under which doctors work are profoundly changed, and it is necessary to meet the growing temptations and the facilities for yielding to them by the creation of an organization with disciplinary powers. One of the most important changes within the last forty years is the growing congestion in the medical profession. In 1913 there were only 1,572 medical students registered in France. The corresponding number in 1932 was 3,125. Again, the growing complexity of medical science has inevitably entailed co-operation between general practitioners and various specialists—a state of affairs providing opportunities for fee-splitting and other illicit financial readjust-

ments between doctors. Lastly, the introduction of State sickness insurance has brought the medical profession into contact with an impersonal, absentee, inattentive paymaster, the cheating of whom in the minds of a few delinquent practitioners is too tempting. It has been argued that the medical associations which most doctors have joined are capable of maintaining discipline within their ranks, and that the proposed Order is superfluous. It is true that more than 20,000 of the 26,500 French doctors are members of some medical association, but Dr. Gadaud argued that the function of a medical association or syndicate is very different from that of a medical Order. The former is concerned with a doctor's rights, the latter with his duties.

New Income Tax Regulations

The new income tax regulations of December 23rd, 1933, have exasperated the medical profession to such a degree that not only the various medical associations, but even the detached and austere Academy of Medicine have protested vehemently. According to the new regulations, a medical practitioner has to keep a book of receipts on which, as well as on the counterfoils, he must enter every day the sums he receives. The receipt and its counterfoil bear identical numbers instead of identical names—this to assure that professional secrecy which is imposed by law on French doctors, on whom heavy damages may be inflicted if, however inadvertently, they give information to a third party about their patients. The income tax inspector is to have access to these counterfoils, and it is easy to see how, posing as a patient, he could check a doctor's income tax return. It is felt that the medical profession has been degraded to the level of tradesmen by this system, which entails the prompt distribution of receipts for any sums received, however trifling. As pointed out by the Vice-President of the Academy of Medicine, Dr. Siredey, at a recent meeting of the Academy, consultants do not, like many general practitioners, have a fixed scale of charges, but temper the wind to the shorn lamb to such an extent that, while accepting a fee of 300 francs from one patient, they leave it to the patient in straitened circumstances to pay what he likes, even if it be only 20 francs. "How shall we be able to convince the income tax inspector of the *bona fides* of our book of records in which a receipt for

¹ *Concours Médical*, February 11th, 1934.

20 francs appears next to one for 300 francs? In his eyes we shall appear as first-class swindlers!" The Academy of Medicine has adopted the following resolution:

"The Academy, wishing to associate itself with the protests of different medical groups with regard to the new fiscal regulations imposed on the medical profession—remembering that doctors consider themselves bound to respect professional secrecy absolutely—protests against these regulations, which appear, on the one hand, to be inapplicable in practice, and, on the other hand, to be even contrary to the spirit of human and public solidarity of the medical profession, which cannot be assimilated in the slightest degree to commercial occupations."

Hospital Congestion and the Well-to-do Patients

The public hospitals of Paris are apt to be so congested that some patients have from time to time to be put up in extemporized beds or discharged too soon. One suggested remedy for this state of affairs is to provide more hospital accommodation. Another is to comb comparatively well-to-do patients out of institutions originally and still intended only for the poor. A recent discussion by hospital authorities in Paris has brought to light certain curious features of the present situation. It has been calculated that approximately a third of the inmates of the public hospitals at the present time are well-to-do and therefore out of place. The doctors on the staffs of these hospitals complain that by having to attend to this class of patient the really poor patient is liable to be pushed aside and the private practitioner is robbed of his dues. In 1925 the municipality of Paris granted 150 million francs to the *Assistance Publique*, which includes hospital services. The corresponding grant in 1932 was 350 million francs! The general practitioner not only suffers from this state of affairs but is also partly to blame for it. He finds it so temptingly easy to shift his difficult private cases on to a public hospital.

England and Wales

The L.C.C. Election

A noticeable feature—and, in the public interest, a very satisfactory feature—of the London County Council election on March 8th is the large number of members of the medical profession who have been returned. There should be no difficulty in staffing the mental hospitals, the Housing and Public Health, and the Hospital Management Committees (to give them their new titles, hitherto somewhat unfamiliar) with medical members well competent to offer sound professional advice to the lay members in those important branches of the Council's work. To take them in the order of their constituencies, Bermondsey (Rotherhithe) has returned Dr. J. A. Gillison (Labour), the junior partner in a firm in that district and a member of the Panel Committee for the County of London: he has not previously sat on the County Council. Greenwich returns Miss Esther Rickards, F.R.C.S. (Labour), hitherto an alderman; she is on the honorary staff of the Lock Hospital and is an assistant medical officer under the Finsbury Borough Council; on the outgoing Council she was a prominent member of the Central Public Health Committee, and displayed especial interest in matters relating to maternity and child welfare. Hackney (Central) has elected Dr. Bernard Homa (Labour), who is a new recruit at County Hall but has experience to his credit as Member of Council of the Metropolitan Counties Branch of the British Medical Association, on the London Panel Committee, and on the Central Committee of the London Public Medical Service. Hampstead sends another new member in the person of Dr. S. Monckton Copeman, F.R.S. (Municipal Reform), the

very well known former medical officer to the Ministry of Health. Dr. Copeman is a member of the Metropolitan Counties Branch Council of the British Medical Association. Kensington (North) returns Dr. Henry Robinson (Municipal Reform), who has already represented that constituency and has been for the last year or two vice-chairman of the hospital management subcommittee of the Central Public Health Committee, as well as chairman of the Bexley Mental Hospital and of St. Peter's Hospital, Whitechapel. He has been for some years honorary treasurer of the Medical Defence Union, member of Council of Epsom College, and Member of Council of the Metropolitan Counties Branch of the British Medical Association; he is now Chairman of the Kensington Division, and last December was elected to the Central Council of the Association. Shore-ditch returns Dr. S. W. Jeger (Labour), a member of the outgoing Council, who is a public vaccinator in his area and chairman of the Public Health Committee on the local Borough Council. Southwark (North) is once more represented by Dr. C. W. Brook (Labour), who comes of a medical family established for some generations at Lincoln (and still notably represented there); he is anaesthetist to the British Dental Hospital, and in general practice at Balham. Stepney (Mile End) sends for the second time Mr. Somerville Hastings, F.R.C.S. (Labour), formerly M.P. for Reading, and well known in London through his connexion with the Middlesex Hospital, where he is surgeon to the ear and throat department. He has been prominent in the Council Chamber on such subjects as tuberculin-tested milk and health propaganda by means of posters, which he wishes to have displayed in the Council's hospitals on the walls of waiting halls, corridors, etc. Westminster (St. George's) returns Dr. Florence Barrie Lambert (Municipal Reform), who has sat for twelve years on the Council, where for the last seven years she has been Chairman of the Central Public Health Committee. The range and quality of the work she has done there is recognized by both political parties, and by none more than by the members of the medical profession, though London as a whole is by no means fully cognizant of how much it owes her. Dr. Lambert was trained as a nurse at the London Hospital, went to the South African War as a fully trained sister, then took up a medical career and attained the rank of Major in the R.A.M.C. during the European War. She was for some years on the medical staff of the Ministry of Health. Woolwich (West) sends up Dr. S. McClements (Labour), another new member with his spurs yet to win and youth on his side. Only one medical member of the late Council is not returned, Dr. Adeline Roberts (Municipal Reform), who sat for St. Marylebone but did not stand again in circumstances which have already been ventilated in the daily press; her absence will be a loss to the County Council, where she has been a valuable member for twelve years. Apparently no medical candidate throughout the County of London failed to secure election—a most remarkable record.

Medical Society of London: Anniversary Dinner

The 160th anniversary dinner of the Medical Society of London was held on March 6th at the Trocadero Restaurant, with the president, Sir John Thomson-Walker, in the chair. In proposing the health of the Society, the Home Secretary, Sir John Gilmour, said that its work was directed immediately to the alleviation of pain and the betterment of mankind. He could speak with a knowledge of the difficulties encountered by the medical profession in peace and in war, as he had come into close contact with its members in the South African and in the late war. Referring to scientific progress in medicine, Sir John Gilmour remarked that the man who did not make experiments or take risks probably did not

good in this world. It was a great help to him in his official work to meet members of the medical profession, from whom he had derived benefit in both public and private life. Sir John Thomson-Walker, in reply, said that they met that evening in accordance with the rules laid down in 1773. At that time there were eight medical societies in London, but this Society was the only one that had survived. It owed its survival to the fact that it was founded by a general practitioner, John Coakley Lettsom, a very active, shrewd Quaker, who saw the danger of a society's being run as a one-man show. Lettsom died in the year of Waterloo, when the Society was forty-two years old. The Medical Society of London gave birth to the Medical and Chirurgical Society, which later became the Royal Society of Medicine. Since the formation of their Society, Sir John said, one of the greatest changes in the medical profession had been the growth of specialism. The dangers of specialism observed in other countries had been avoided here owing to the robust common sense of its practitioners. Sir William Willcox, in proposing the health of the guests, said that the Society was very glad to have with it Sir John Gilmour, who was not only a distinguished politician but a lover of country life. The Home Office had one bond in common with the medical profession—they both investigated crime. Welcoming Lord Macmillan, the speaker referred to the great efforts he had made on behalf of the University of London. Among the other guests Sir William alluded to Sir A. Grant, one of the founders of the Scottish National Library. In a witty speech of reply on behalf of the guests, Lord Macmillan said that he was especially glad to meet distinguished members of another profession, and such contact was of immense benefit to both: they had a great deal to learn from each other. In his work for the University of London he had found that it was one of the greatest medical universities in the world, and in this connexion he welcomed the new Post-Graduate School of Medicine at Hammersmith. If the Empire was to continue in strength, Lord Macmillan continued, it needed to acquire professional ideals and aspirations: the bonds of the spirit must be strengthened by the professions. In the Dominions the classes who governed were the doctors, the lawyers, and the accountants—the professional classes.

Bristol Health Congress

In connexion with the Health Congress, which is to be held this year at Bristol from July 9th to 14th, the Royal Sanitary Institute announces the following among other presidents of sections and conferences. Professor W. W. Jameson, M.D., Section on Preventive Medicine; Dame Janet Campbell, M.D., Section on Maternity, Child Welfare, and School Hygiene; Professor J. T. Share-Jones, F.R.C.V.S., Veterinary Hygiene Section; Mr. Frank Lewis, Section on National Health Insurance; Dr. L. H. Lampitt, Hygiene of Food Section (arranged in conjunction with the Food Group of the Society of Chemical Industry). The Lord Mayor of Bristol will preside over the Conference of Representatives of Sanitary Authorities, and Dr. Charles Porter over the Conference of Medical Officers of Health.

The Infirmary Appeal at Leeds

The appeal which was launched some months ago by the General Infirmary for the large sum of £250,000 is meeting with an amount of support which encourages the authorities to look forward with hope to the time when all the money may be obtained. The amount given or promised up to date is £133,364, and steady additions are noted every week. Many of the surrounding towns are interesting themselves in the matter, and are making special efforts to help. It is right they should do so,

since the statistics show that there are many areas outside the borough of Leeds from which large numbers of patients come, or are sent to the Infirmary, but which contribute very little to its support. It is very encouraging to find that this is being more fully recognized now than it has been in the past. The proud title of "The General Infirmary at Leeds" (not the "Leeds General Infirmary") should carry with it not only great responsibilities outside the boundaries of the city but a proportional degree of financial support. Meanwhile, careful thought is being given to the plans for extension, and in this, as happily is always the case in Leeds, the opinion of the honorary staff is being given every consideration. In the *Magazine* of the Medical Society of the University, Mr. Charles Lupton, writing from an experience of more than half a century and from a fullness of knowledge which, in Leeds at least, must be unique, expresses himself as follows:

"So far as finance is concerned, I think we are passing into a new era. The fact that our hospitals are giving to the poorest a safer and better relief from their sufferings than can be obtained by the highest in the land by treatment in their own homes or in a nursing home, is already well known to the working classes, and the news is spreading rapidly."

This is, indeed, very true, but in the extension scheme the needs of those who are not deemed suitable for purely gratuitous treatment, or who cannot afford the heavy expenses of private treatment in a nursing home, are not being overlooked; and here again Mr. Lupton may be quoted, for he continues as follows:

"The new pay wards (one of the most important of the proposed extensions) will only be a first step in the ladder. I have a strong belief that the next change we shall see will be a demand for much greater paying accommodation."

As the requirements of the Infirmary, through the medium of these columns, may be brought to the notice of that large number of medical men who look back with pleasure, gratitude, and pride to their student days within its walls, it is hoped that they will bring the claims of this important part of their Alma Mater before those who may be in a position to subscribe, and also add to the goodly number of those former students who have already responded to the appeal.

District Nursing in London

The annual meeting of the Central Council for District Nursing in London was held on February 22nd, when the nineteenth annual report, for the year ended December 31st, 1933, was adopted. The scheme for the home nursing of persons coming within the scope of the Public Assistance Department of the London County Council has now been in operation for over a year. The total number of cases in receipt of relief or referred from L.C.C. hospitals or by district medical officers for the year ended September 30th, 1933, was 3,243, and the visits paid to these cases totalled 139,845. The Central Council received a grant of £200 from the trustees of the London Parochial Charities, to enable nurses who had difficulty in finding the examination fees for the C.M.B., thus increasing their usefulness in their profession and to the area in which they work. Since these grants were first inaugurated forty nurses have passed this examination. District nursing has gradually extended in Middlesex. A new association has been formed to include Golders Green estate, some adjoining poor streets, and the Council estate of Clitherhouse. The district associations of Wealdstone and Harrow have amalgamated. The East London Nursing Association has built a new and commodious home, and others are projected elsewhere. Grants and subscriptions have been received for distribution from the City Parochial Charities, the Peabody, Guinness, and Samuel Lewis Trusts, and the London County Council.

In the case of the last named a subsidy of £1,000 was received quarterly in respect of the district nursing of Poor Law cases. The allocations were determined on the basis of the number of visits paid, and this enabled a distribution to be made of approximately 6½d. a visit for the first, second, and fourth quarters, and just over 7d. for the third quarter. The cost of a nursing visit in London has been estimated to average about 1s. 4d. The representatives of the British Medical Association on the Central Council were Mr. Comyns Berkeley and Dr. William Paterson, and Dr. Christine Murrell, until her death last October.

Alcohol and Motoring

Mr. W. McAdam Eccles, on taking the presidential chair of the Temperance Collegiate Association on March 7th, devoted his address to the question of alcohol and motor vehicle control. He began by emphasizing that the pedestrian as well as the motorist who failed to avoid a so-called "accident" because his reaction time was dulled by alcohol circulating in his blood was blameworthy. The public should realize that it was not always the driver who was responsible, and the number of people walking in the road under the influence of drink was perhaps greater than the number of drivers whose perception was blunted from the same cause. Mr. Eccles further pointed out that alcohol in all its stages of influence upon the nervous system was not a stimulant, but a narcotic, meaning a substance inducing stupor or drowsiness and some deprivation of sense. One drop of alcohol in 1,000 drops of blood (0.1 per cent.) produced symptoms, three drops produced real drunkenness, and five drops such stupor as to bring about the possibility of death from acute alcoholic poisoning. It was not the amount taken into the stomach, but the proportion circulating in the blood which induced the state of being "under the influence." He claimed that all persons taken under this suspicion to the police station should have the percentage of alcohol circulating in their blood estimated, either by the police surgeon or the doctor of their choice, or both. If the percentage was over 0.1 it could be definitely stated that the person had sufficient alcohol circulating in the blood to render him "under the influence" of drink. Some recent extraordinary statements, even from the judicial bench, showed how greatly a really scientific and yet practical test was needed. Certain administrators of justice were evidently still incapable of seeing the difference between being "under the influence" and being drunk.

In a brief discussion Dr. Alexander Baldie, a divisional surgeon of the Metropolitan Police, said that the amount of alcohol in the blood had to be related to the idiosyncrasy and temperament of the person concerned. The element of fatigue in particular came in, and bulked to nearly the importance of alcohol. It happened repeatedly, said Dr. Baldie, that men such as commercial travellers drove about the greater part of the day, eating little or nothing, and after refreshing themselves at the wayside inn with alcohol on an empty stomach found that the combined effect of alcohol and fatigue led to loss of control. Fatigue was only an illustration of a number of conditions which rendered a man susceptible, and which made it difficult to lay down the absolute rule that alcohol should be forbidden to all persons driving, irrespective of other conditions. Mr. McAdam Eccles, while agreeing with Dr. Baldie that the matter was one for joint conference by psychologists, neurologists, and sociologists, said he was sure that Dr. Baldie would not uphold the view that alcohol was the best antidote to fatigue; in any case the serious accidents of which one read in the newspapers were due less often to fatigue than to unwise indulgence on social occasions, into which no element of weariness after bodily or mental labour had entered.

Scotland

East Fortune Sanatorium

The eleventh annual report by Dr. Charles Cameron, medical superintendent of the sanatorium maintained at East Fortune by the South-Eastern Counties of Scotland General Sanatorium Board, points out that for the year ending May, 1933, the weekly cost of maintenance per patient was 36s. 7d., which compares favourably with an average cost in the majority of similar institutions in England of between 40s. and 70s. The total daily average number of patients was 205. Patients discharged from the institution numbered 209; of these 32 per cent. were apparently recovered, 47 per cent. improved, 6 per cent. stationary, and 4 per cent. worse; 10 per cent. died. Of the twenty-two deaths fifteen had been in lung cases. On the general subject of tuberculosis the report points out that the disease is not simply one of a limb or organ, but of the whole body—a fundamental point which has only recently been completely grasped. Accordingly the early days of the present century saw much surgical interference with tuberculous patients, which was often productive of bad results. The sanatorium treatment of tuberculosis of the lungs pointed the way to the important part played by raised body resistance in the healing process.

Edinburgh Dental School

The report presented to the forty-second annual general meeting of the Incorporated Edinburgh Dental Hospital and School, with Professor Sydney Smith presiding, showed that during the year there had been 150 students attending hospital practice as against 139 in the previous year, and that thirty-one new pupils had been apprenticed. During the year forty-two students had had their fees paid in whole or in part by the Dental Board. The income had amounted to £6,177, and there was a credit balance of £14 18s. Reference was made to the resignation from the office of dean of Dr. William Guy, on September 30th last. Lieut.-Colonel Finlayson had acted as dean for three months, and Mr. Arthur Cyril William Hutchinson, Manchester, had been appointed to the post as from January 1st, 1934. In connexion with this appointment the Dental Board had offered a grant of £500 per annum, for a period of five years, towards the salary of the dean as a whole-time teacher of clinical dental surgery. With regard to the work of the Dental Hospital there had been 12,788 conservation cases, 1,948 prosthetic cases, and 5,952 extraction cases.

Edinburgh Orthopaedic Clinic

At the annual meeting of the Edinburgh Orthopaedic Clinic, which was held on February 20th, Mr. Charles Guthrie, who presided, said that the object of the clinic was to provide massage, medical gymnastics, medical electricity, and ultra-violet light treatment for people of limited means at moderate fees. During the year 338 patients had been admitted, and 6,980 treatments had been given as against 6,841 in the previous year. The revenue had been £709, but there was a deficit of £202 on the year's working. Miss Gertrude Herzfeld said that the work of the clinic had begun in a single room with one masseuse; at the present time there were fifty patients, daily under treatment and eight masseuses, who worked four hours daily. The work had increased steadily during the past seven years, and there was a long waiting list of over sixty patients, some of whom would require to wait for about four months before commencing their treatment.

Reports of Societies

HAEMATEMESIS

At a joint meeting of the Sections of Medicine and Surgery of the Royal Society of Medicine on March 7th, with Professor G. E. GASK, president of the Section of Surgery, in the chair, there was a discussion on haematemesis.

Dr. ADOLPHE ABRAHAMIS enumerated the causes of haematemesis, naming peptic ulcer, malignant and benign gastric tumours, cirrhosis of the liver, splenic anaemia, and the haemorrhagic diathesis. The symptom was not, he said, common in cancer of the stomach, and innocent tumours were rare. Occasionally blood from the nose or the lung might cause uncertainty, but frank haematemesis, and the accompanying blood in the stools, offered no difficulty in diagnosis. The subject of haemorrhage from peptic ulcer had been discussed in 1923; since then advances in haematology had affected the treatment. A degree of anaemia that at one time would have excited panic was now regarded with equanimity. There was bound to be a discrepancy of mortality figures between those favouring surgical intervention and those preferring conservative treatment. Certain types of patient demanded surgical measures—for example, those with degenerate arteries which could not contract. Others, such as oozing cases, offered greater difficulty. One type of ulcer patient showed a special tendency to bleed, and authorities differed as to whether surgery was particularly valuable for this group. Apart from peptic ulcer and splenic anaemia the indications for surgery were few, and splenectomy did not always prevent or retard cirrhosis of the liver and subsequent grave haematemesis. Gastric bleeding was sometimes followed by pyrexia, which might be due to stagnating blood clot in the intestine, or to activity of the ulcer. Blindness following haematemesis might be both complete and permanent; its mechanism was obscure.

Mr. G. GORDON-TAYLOR mentioned, as additional causes of haematemesis, non-calculous cholecystitis, fibroid appendix disease, and rare cases of intestinal stasis. None of these demanded urgent surgery, which should only be employed after definite proof of the existence of chronic ulcer. Prophylactic surgery could not guarantee success, unless it took the form of resection. Mortality increased enormously after each successive haemorrhage, and operation should be performed after the first. It was more convenient to wait until the bleeding ceased, but there was no certainty that it would cease. Figures from the Middlesex Hospital showed a mortality rate of 78 per cent. for second haemorrhages, but a slightly lower death rate for medical than for surgical treatment in bleeding ulcers. Patients with stenosis, mid-gastric narrowing, perforation, or large, deep, or chronic ulcers would almost certainly die if left alone. The decision must be made at once: early enterprise was the most certain prelude to success. Local anaesthesia and abundant blood transfusion must be used, and as little anaesthetic given as possible.

Dr. T. IZOD BENNETT agreed with Mr. Gordon-Taylor in his plea for co-operation between physician and surgeon, and in his selection of cases urgently calling for consultation with a surgeon—namely, chronic peptic ulcer and stenosis. Unfortunately these formed but a small proportion of all cases of haematemesis. The vast majority of cases of haematemesis seen in hospital ought never to have been admitted; they had been moved through mistaken judgement or on account of bad home circumstances. Grave cases of gastro-intestinal bleeding should not be moved. Statistics from hospitals should therefore not be quoted in a discussion of the relative advantages of surgical and medical treatment; they represented only the very worst cases. Dr. Bennett discussed seven cases of fatal haematemesis in his experience; only one, he felt certain, could have been saved by surgery. The indications for operation were exceedingly rare. The proper medical

treatment included meticulous care for at least a week: absolute withdrawal of anything by mouth for thirty-six hours; morphine in sufficient doses to produce twilight sleep for the same period; rectal salines; and most careful nursing night and day. Food and drink should then be restored most cautiously, with constant observation of the pulse and stools. Normal saline by mouth was the first thing to give.

Mr. A. S. MORLEY spoke of the improved transfusion service, and said that haemorrhage from acute ulcers was the province of the physician. Since some 10 per cent. of those with haematemesis died there was a grave problem for consideration. Many patients were unfit for thorough investigation to prove the presence of chronic ulcer, but the clinical history was a valuable diagnostic indication, though it would not distinguish between gastric and duodenal ulcer. Rules could not be formulated to fit every case, but serious bleeding was usually due to erosion of a large vessel, and death followed a series of bleedings. Collapsed exsanguinated patients should not be operated on, nor should interference be postponed for months. If the diagnosis was reasonably sure the surgeon should aim at getting the patient fit for operation as soon as possible, by the medical means mentioned by Dr. Bennett. It was safer to operate than to wait, once the circulation had reached a favourable condition. Indirect measures were likely to be futile; the only satisfactory operation was some form of excision. These patients should not be left to doctors of inadequate experience. Greatly swollen, red, and congested appendices caused haematemesis. Early post-operative haematemesis was due to failure of technique, and remotely to anastomotic ulcer. Splenectomy might offer the only hope in cases of thrombocytopenic purpura, but it would not cure oesophageal varices.

Dr. R. S. AITKEN emphasized the importance of distinguishing between mild and grave cases, and brought forward figures from the London Hospital showing an appreciable mortality in serious cases treated medically. He stressed the value of transfusion.

Professor C. A. PANNETT said that statistics were concerned with series which were not really comparable. He advocated early surgery—before grave anaemia had resulted from repeated bleeding. The best guide to fitness for operation was the amount of blood the patient had lost; 50 per cent. was about the limit. Operation should never be performed with a pulse rate above 100 from haemorrhagic shock. The procedure should be the smallest possible, provided that the ulcer could be removed.

Dr. G. GRAHAM said that repeated transfusion might be necessary. If the haemoglobin was below 40 per cent. blood should be given. Sometimes the haemoglobin dropped next day, because the patient was able to dilute the blood and make up the volume. An estimation should therefore be made directly after transfusion; if it did not go up, at least temporarily, more blood was needed.

Mr. H. PATERSON thought that very few of these patients died if left alone, and believed in medical treatment. The important thing was absolute rest. The teaching that egg and milk might be given had done much harm. In most cases the blood came from general gastric oozing, not from an eroded vessel. Surgery in acute haemorrhage was totally unnecessary, and very rarely justifiable.

The CHAIRMAN, summing up, thought there had been general agreement that patients should not be moved, and that operation should be rare. A proportion, however, did reach hospital; some died, and some could have been saved by surgery. Blood transfusion helped both medical and surgical treatment. There was division of opinion about the time of surgical intervention; the risk to life was enormously increased after any repeated haemorrhage. The surgeon must find the bleeding point and secure it, and this was best done by some form of resection. It was clear that there was no golden rule, and a very nice judgement was required to select cases for surgery. The way to choose was by careful co-operation and careful examination.

CLEAN MILK IN DUBLIN

At a meeting of the Section of Pathology of the Royal Academy of Medicine in Ireland, held in the Royal College of Physicians on February 23rd, with the president, Dr. J. McGRATH, in the chair, Professor J. W. BIGGER read a paper entitled "Fifteen Years' Progress in the Clean Milk Campaign."

He said that in 1919 he had found milks sold in Dublin with total counts of up to 73 million bacteria per c.cm. The best month of the year was September, in which the average number of bacteria found in the milks examined was 289,000. Thirty-five per cent. of the milks tested during the year contained over one million bacteria per c.cm. Seventy-three per cent. contained *B. coli* in 0.01 c.cm. or less. During the eight years 1926-33 319 milks had been examined in the School of Pathology, Trinity College. The highest count, which was found in 1926, was 50 million per c.cm., and the next highest, in the same year, 7,900,000. Since then the counts were much lower. Out of 129 milks examined in the years 1932 and 1933 only two had exceeded one million bacteria per c.cm. In each of the last two years three counts of under 1,000 per c.cm. had been obtained. The improvements in the total counts were further illustrated by the medians and weighted means. The weighted mean for 1926 was 782,000 and for 1932-3 40,000. In 1926-7 31 per cent. of the milks fell within the limits of Certified milk, and 57 per cent. within those of Grade A milk. In 1932-3 62 per cent. fell within the Certified and 85 per cent. within the Grade A limits. In 1926-7 7 per cent., and in 1932-3 29 per cent., contained no *B. coli* in 1 c.cm. In the earlier period 45 per cent. contained *B. coli* in 0.01 c.cm. or less, as against 25 per cent. in the later period. Improvements were also shown by the results obtained in the routine examination of the milk supplied to a Dublin hospital. Finally, Professor Bigger emphasized that, despite the great change for the better in the Dublin milk supply, legislation was urgently required.

The PRESIDENT, in thanking Professor Bigger for his paper, said that he was largely responsible for the great improvement which had taken place in the milk supply of Dublin in the last fifteen years. The results of the work were so good that he thought Professor Bigger could feel that, although it had been a very big task, his work in the matter had been well worth while. He noticed that all the samples which Professor Bigger had examined had been morning milk, and he thought that if they had been evening samples the bacterial count might have been very different. If the count was one thousand bacteria in the morning, he thought it might have increased to one million by the evening. The question of pasteurization had always been under discussion. He personally believed that pasteurization was a very good thing. The types of apparatus used for pasteurization had become much better in recent years. He asked Professor Bigger what proportion of the milk supplied in Dublin was Grade A certified milk, compared to the total quantity of milk which was produced.

Mr. P. F. DOLAN said that much credit was due to Professor Bigger for the work he had done. He thought there was a great deal in favour of pasteurized milk, and felt that in time a considerable proportion of the milk supply of Dublin would be pasteurized. Some years ago one was told by some people that it would be quite impossible to set up a tubercle-free herd of cows, let alone to maintain it. Eight or nine years ago the Corporation of Dublin had established a tubercle-free herd at Crookslin Sanatorium, and at present the herd was tubercle-free and also abortion-free. Many farmers in the Free State could, if they wished to do so, set up a tubercle-free herd and an abortion-free herd and keep them free. A lot of the trouble was, he felt, due to the impossibility of bringing the consumer in touch with the producer. There were many people who believed that cold or low temperature killed organisms, and that if milk when delivered was put into a refrigerator all the organisms would disappear. In another few years he thought it would be possible to reach the ideal with regard to a milk supply by getting milk which had not

been touched at all by human hands. The standard of milk machines was improving, and they were now sterilized regularly twice a day. Legislation in connexion with the milk supply was extremely important, and he felt that there was a good deal of misunderstanding regarding this question. Legislation was required to protect the milk vendor who was really careful about his dairy and did things properly. It was essential that the consumer should have an assurance that the milk which was sold as Certified was really certified.

Professor W. D. O'KELLY said there was no doubt that Professor Bigger was the pioneer of clean milk in Dublin. He thought it should be remembered that people who came with milk to be examined did not usually bring dirty milk. He felt that there was still quite a lot of dirty milk sold as clean milk. In the laboratory at University College counts of two to three hundred organisms per c.cm. were obtained last week. Cold weather was, of course, very favourable for low counts. He asked what percentage of the milk sold in Dublin was pasteurized.

Dr. J. A. HARBINSON said that in his public health work he had very early come up against the milk problem, and Professor Bigger's work had been of the greatest help to him. He was glad to see from the figures which Professor Bigger had put on the screen that there was a steady improvement as reflected by the weighted mean. In many other places where he had seen the figures he had found it very difficult to ascertain exactly what progress had been made. He thought the production of milk in the rural areas as well as in Dublin itself had to be considered. In the rural areas the vendors' idea was to produce as much milk as possible, and they had no regard for whether it was clean or not. Not only the large producers but also the small ones had to be considered, and it was necessary to think of what could be done to improve the cleanliness of milk which was supplied by the small producers. It was necessary to make the producer realize what was needed in order to get the best production, and it was essential to protect the consumer against dirty milk. When dealing with legislation it should always be borne in mind that legislation would be produced if a public request demanding its production could be obtained. Legislation was necessary which would provide a standard of milk, but that standard must be one which would appear reasonable both to the producer and to the consumer. A good deal of education would have to be carried out to show the small producers how to produce milk which would come up to the standards required by legislation. Even when it was possible to have tubercle-free milk introduced into every home in Dublin there would still be the necessity for education regarding the care of milk when it reached the homes.

Dr. W. R. F. COLLIS referred to the number of children who got tuberculosis and other infections from a bad milk supply, and mentioned a recent paper by Dr. Moncrieff, in which the author stressed the difference in the milk supply in Germany and in England, and referred to the fact that there was a good deal more bovine tuberculosis in England than in Germany. Much more pasteurized milk was drunk in England than in Germany. He felt that it was necessary to get the ordinary poor, uneducated mother to realize that milk was not really safe as a food for children unless it had been boiled or was guaranteed as being tubercle-free. If legislation was introduced, he personally would like to see milk divided into two classes—safe and unsafe. Professor T. T. O'FARRELL asked Professor Bigger if he had tested samples for antiseptics, and how far it was necessary for a bacteriologist to test for antiseptics before he analysed milk, and if pharmaceutical chemists tested for antiseptics. He also asked how far Professor Bigger tested his *B. coli* out. In his view milk should not be handled at all, but this was impossible at present, when there were so many small producers who had to handle it. For the time being he regarded pasteurization as the safest method, though there was much difference of opinion as to whether milk was damaged by pasteurization or not. Dr. R. E. STEEN asked what were Professor Bigger's

views regarding the boiling of milk, and if he thought that an educated mother should be told to boil milk even when it was obtained from a tuberculin-tested herd. He also asked for how long the milk should be boiled, and what was the absolute margin of safety for destroying every pathogenic organism present in it. Dr. W. H. ASHMORE referred to the great importance of legislation, and said he thought a great deal would be accomplished if one could be absolutely certain that milk which was labelled Grade A or Tubercle-Free was really tubercle-free. Until it was made a serious offence to use a milk bottle for any other purpose except for holding milk not much progress would be made with pasteurization.

Professor BIGGER, in reply, said that if milk was going to be pasteurized it need not be clean. It was now possible in Dublin to get really clean milk. Fifteen years ago this had not been possible. He had not paid particular attention to antiseptics, but had never found them present.

EARLY OPERATION FOR CHOLECYSTITIS

At a meeting of the Liverpool Medical Institution on February 22nd, with the president, Dr. J. MURRAY BLIGH, in the chair, Mr. PHILIP HAWE read a short paper on "Early Operation in Cases of Acute Cholecystitis."

Mr. Hawe considered that the time had arrived to replace the "medical expectant" policy in these cases by the more satisfactory method of immediate operation. The pathology of the condition was discussed and the frequent occurrence of necrosis, with spread of infection, due to pressure of the stone or vascular interference, was stressed. In over 90 per cent. of these cases stones were present, and even if resolution occurred fresh stone formation was to be expected. Moreover, in the early stages of acute cholecystitis the infection was mild and confined to the gall-bladder—delay resulted in rapid progress of the infection both inside and outside the gall-bladder. Pancreatitis and pericystic abscess and other serious complications were much more frequent than was generally recognized. From the pathological point of view the benefits of early operation appeared certain. A series of operations in forty-five cases of acute cholecystitis was analysed. In the majority, except the severe grade, expectant measures were at first adopted, but it was found that whereas early operation in ten cases in this series carried no mortality, in the thirty-four cases which failed to subside on expectant lines there were four deaths. In this group of delayed operations serious complications often called for performance of the less satisfactory operation of cholecystostomy. The following conclusions were reached: (1) Early cholecystectomy is a most satisfactory procedure—if conditions are unsuitable early cholecystostomy or partial cholecystectomy gives good immediate results. (2) Expectant treatment frequently leads to a delayed and difficult operation in the presence of serious complications. (3) In acute cholecystitis the serious nature of local complications in a most vulnerable area involving liver and pancreas carries grave risk which can be avoided by early operation.

Mr. C. A. WELLS agreed that in a majority of cases it was possible at an early operation to carry out radical procedures and, very commonly, with less difficulty than in the case which had been left over for an interval to settle down, since in that recovery period dense adhesions were formed. He considered there was little to be gained by preliminary investigations, since the practical precautionary measures which it was possible to adopt were three—namely, the administration of glucose and calcium and the employment of a non-toxic anaesthetic. He suggested that these measures could be applied with equal facility in the early case. It had been his practice for a number of years to operate on these cases early rather than late, and he had so far not had cause to regret this plan. The existence of early jaundice seemed a good indication for operation, since it was impossible to predict the progress of the condition, and once it became well established it constituted a very grave factor, seriously endangering the prospects of recovery. He looked forward to the day when the accepted attitude

would be "immediate operation in the absence of indications to the contrary," rather than the present teaching, "expectant treatment and delayed operation in the absence of indications to the contrary."

'Self-administered Anaesthesia in Childbirth

Dr. R. J. MINNITT described a method of self-administration of nitrous oxide gas and air for the midwifery of general practice. Photographs were shown of a new apparatus devised for this purpose, and it was explained. The principle of its action was that the mixture inspired was constant, and only available for intake by the patient on inspiration. The average amount of gas consumed was thirty-five gallons an hour, and the analysis of the mixture inhaled was 35 per cent. nitrous oxide in air. Owing to the analgesia the mother received great relief from pain, amnesia being produced in most cases. No ill effect had been observed on the child. The apparatus had been tried in two institutions: (1) the Wellhouse Hospital, Barnet, Herts, by Dr. John Elam, under the supervision of Mr. Roland Segar, medical superintendent; and (2) the Liverpool Maternity Hospital, by Dr. Hilda Garry, under the direction of Dr. R. J. Minnitt, honorary anaesthetist, a grant having been obtained for this purpose through the National Birthday Trust Fund. Dr. Elam's report and that of Dr. Segar were both read, and an analysis of sixty-four successful cases, with one failure owing to non-cooperation of the patient, was given.

Dr. HILDA GARRY showed a photograph of the machine used by her in hospital, and analysed 121 cases who had received N₂O and air analgesia. There were eighteen failures in the series, owing to causes not directly connected with the administration. She pointed out the beneficial effects of the method upon mother and child, and showed that: (1) In the first stage of labour pains were relieved and apprehension removed. (2) In the second stage the same effect was observed without interfering with the normal voluntary effort. She also stated that the mothers showed much less stress and strain of labour than was usual without analgesia, and that no appreciable alteration in the mother's pulse or the foetal heart was found.

Professor LEYLAND ROBINSON said that ever since the days of Sir James Y. Simpson attempts had been made to find an easy and safe method of relieving the pains of childbirth, but up to the present time no completely satisfactory method had been discovered. The anaesthetic or analgesic must not only be innocuous to the mother and the child *in utero*, but it must have no effect upon the delicate functions of the parturient uterus; and since at least 50 per cent. of all confinements were conducted by midwives in the absence of a doctor it was essential that the apparatus should be simple, portable, and fool-proof. Dr. Minnitt and Miss Garry had devised a method which achieved all these objects, and all obstetricians would view further experiments with the greatest interest and offer every facility for the adoption of the method in domiciliary midwifery.

Dr. JOHN HALTON said it must be remembered that although chloroform and ether had been used in maternal anaesthesia since their inception, these drugs had more affinity for foetal tissues, especially the liver, than the mother's. Self-administered gas and air was probably first used about 1908, but was abandoned on account of foetal distress. It must never be forgotten that nitrous oxide was a dangerous anaesthetic in midwifery. A progressive anaemia, often difficult to recognize, occurred frequently if this method was used by the inexperienced, and Greene had shown that this could cause a direct central respiratory failure and a reflex cardiac rhythm acceleration. On the other hand, it was generally understood that a gas-air mixture of at least 40 per cent. was necessary for a true analgesia. If Dr. Minnitt had succeeded by his machine in avoiding these dangers and at the same time produced a satisfactory analgesia then a new era in obstetric anaesthesia had commenced. Dr. J. GRAHAM MARTIN said that the administration of such an anaesthetic by the patient really would be of great assistance to a general practitioner in midwifery work. He inquired when a "light-weight" apparatus

could be expected to be for sale and light-weight cylinders could be obtained, as a medical man's outfit for maternity cases was heavy enough already. Dr. ARTHUR A. GENMELL said that from his own observations he was satisfied that the method described by Dr. Minnitt gave great relief, and frequently produced a complete amnesia of the delivery.

Fractures of Neck of Femur

Mr. W. J. EASTWOOD read a paper on "Fractures of the Neck of the Femur," based on the results in forty-one patients who replied to a follow-up. The various methods of treating a recent fracture were considered, emphasis being laid on the value of a walking calliper and early walking in the type of patient who was too old and in too poor a condition to warrant any treatment designed to obtain bony union. The causes of failure of the Whitman method were considered, and the importance of first obtaining full length in the affected limb, and the absolute necessity for good internal rotation at the site of fracture, and not at the joints of the foot and knee, were stressed. Provided these details were carefully observed the Whitman method still offered the best chance of bony union in the hands of most surgeons, other methods requiring too high a degree of surgical skill ever to be universally popular. In old ununited fractures the best treatment was the Lorenz subtrochanteric osteotomy, altering the line of weight-bearing so that weight was transmitted directly on the shaft of the femur and not through an unstable fibrous union. X rays and details of the end-results of forty-one recent and nineteen ununited fractures were given.

Mr. R. WATSON JONES said that he had operated on twenty-eight cases of high fracture of the neck of the femur using a stainless steel Smith-Petersen nail, introduced by a special technique which solved all the difficulties of accurate centring of the nail. The operation was still a difficult one, but the results were vastly superior to those of the Whitman plaster method. (1) The mortality was very much lower: in twenty-eight patients of 50 to 80 years of age there was only one post-operative death. (2) By the Whitman method it was generally agreed that bony union of subcapital fractures was only gained in 40 or 50 per cent. of cases. In his series of cases treated by operation 90 per cent. had united by bone. (3) By the Whitman method, even in the 40 per cent. of cases uniting by bone, the femoral neck was shortened and hip movement was therefore limited. With the greater fixation of the nail this did not occur, and excellent hip movement was retained. (4) The knee-joints of old patients were often arthritic, and became painful and stiff if immobilized in plaster. No plaster was necessary with the nail. (5) There was no doubt as to the serious discomfort of a plaster spica in elderly patients. After operation, on the other hand, patients sat up in bed, moving their limbs; there was no discomfort and their only difficulty was to know why they were not allowed to get up and walk.

Mr. T. P. McMURRAY agreed with the conclusions that Mr. Eastwood had come to regarding the benefit of treatment of fractures of the neck of the femur in plaster. He stated that the proportion of 80 per cent. bony union following this treatment was a very much higher percentage than had been shown in any other clinic. He agreed also that in regard to the treatment of ununited fractures of the neck of the femur, nothing that had yet been devised could approach in efficacy the operation first described by Lorenz as a bifurcation osteotomy of the femur.

Mr. E. N. WARDLE said that Mr. Eastwood's plea for the treatment of the patient as such and not as a mechanical problem appealed to him considerably, but it applied both ways. He felt that most patients preferred an operation followed by comparative freedom to spending three months fixed in plaster, and therefore thought that fixation of a subcapital fracture of the neck of the femur by a Smith-Petersen nail was the best form of treatment. With regard to risk, any patient who was fit for manipulation under an anaesthetic could stand the operation. He did not think Mr. Eastwood laid sufficient

stress on the nursing difficulties of the Whitman method, particularly that of keeping the elderly patient free from chest complications.

ENDOMETRIOMA OF ABDOMINAL WALL

At the February meeting of the Midland Obstetrical and Gynaecological Society, held at Birmingham, with the president, Dr. C. E. PURSLOW, in the chair. Professor BECKWITH WHITEHOUSE showed two clinical cases of ulceration of the vulva for diagnosis, and these were discussed. Dr. MITCHELL read a paper on some aspects of the chemical composition of haematocolpos fluid, and Professor WHITEHOUSE a short communication on a case of sarcoma botryoides with recurrence after twenty-three years.

Mr. T. C. CLARE described a case of endometrioma of the abdominal wall following Caesarean section eighteen months previously. He excised a small tumour from the scar, superficial to the rectus sheath, which showed typical microscopical appearance of an endometrioma. Professor WHITEHOUSE mentioned two cases of the condition. The first patient menstruated regularly through the scar of an old-standing ovariectomy incision—she had a pelvic endometriosis too extensive for operative removal. He excised the ulcer, and all her other symptoms cleared up with deep x-ray therapy. The second case, which had all the typical microscopical appearance of endometrioma, occurred in a male after appendicectomy and drainage. He thought that the theory of peritoneal metaplasia accounted for the origin of some of these cases. Professor STATHAM said he had met with five of these cases, of which two were endometriomata of the umbilicus occurring without any previous operation, one followed Caesarean section, one a myomectomy, and one a radical cure of a hernia involving the round ligament. Mr. R. L. E. DOWNER described two similar cases, the first being an implantation growth in the scar of the abdominal hysterotomy for hydatidiform mole, and the second a tumour the size of a cherry in the vaginal wall at the fourth month of pregnancy. This disappeared as pregnancy advanced but had reappeared six months later. Mr. LOCHRANE said that these growths always shrank after all ovarian tissue was removed or destroyed. He had excised one five times, with recurrence each time.

THE PARENT, THE SCHOOL DOCTOR, AND THE HOME DOCTOR

The need for greater reciprocity between parents, consultants, home doctors, and school authorities, especially in matters relating to health, was the subject of a discussion at the annual meeting of the Medical Officers of Schools Association on March 2nd.

The discussion was opened by Sir MONTAGU FOSTER, head master of Stubbington House, Fareham, who remarked on the blindness of parents to their children's defects, such as curvature, short-sightedness, and flat feet. On the other hand, the schoolmaster was too apt to label a boy stupid when the real trouble was some remediable physical disability; while the school doctor—he was thinking particularly of preparatory schools, where it was impossible to have a whole-time medical officer—could only proceed on what the boy told him (which was not always reliable), or what the master told him, or what he might have learned in correspondence with the parents. The most important thing was that the school doctor should be able to see the boy as others saw him, in the ordinary activities of the school, especially in the common room. But what chance had the doctor who was only called in from outside when a pupil was reported sick? He urged that there should be a medical history sheet beginning with the boy's first day at school, and containing a note of all ailments, as well as measurements and personal peculiarities. Sir Montagu Foster mentioned two or three cases in which a boy had perceptibly suffered through the fussiness of

his mother, and when the mother was brought to see the error of her ways, and left the boy alone, he developed normally.

Dr. H. C. CAMERON spoke of the difficult task of the school medical officer in framing a report, which must be careful but not alarmist, in the early stages of an illness; also in having to deal with one or more members of a family who had not chosen him as doctor, but to whom he was an appointed person, a stranger to the parents, and ignorant of the home surroundings. It would be all to the good if the school doctor could meet the mother, good for the mother because some latent hostility on her part might be dispelled, and good for the doctor because a knowledge of the type of mother would help him in studying the child. As things were, if parents and school doctor did meet, it was usually at some time of crisis, when the personal situation was difficult. One school doctor of his acquaintance followed the useful plan, when a pupil was ill at school, of writing an explanatory letter, using medical terms, to the home doctor, but sending it, with a covering letter, by way of the parents. Dr. Cameron also spoke of the peculiar difficulties which arose owing to the popular dissemination, in these days, of medical knowledge. When King Edward had appendicitis the editor of a great Scottish daily telephoned Dr. Cameron's father to learn what this disease was; nowadays it was a boggy that kept mothers awake at night whenever their boys had a pain in the stomach. In his own childhood earache was considered a painful thing that would be all right in the morning; "nowadays an oto-rhino-laryngologist, armed to the teeth, rose at 2 a.m. to puncture the drum." Often, however, the schoolmaster saw an entirely different individual from the boy as he was at home, and no doubt he felt that the mother was fussy and exaggerative. Nothing was worse for the child than to think there was antagonism between the parents and the school.

Dr. G. E. FRIEND of Christ's Hospital said that occasionally he had to complain of want of reciprocity on the part of the home doctor. Family practitioners did not always seem to remember that a whole-time school doctor became, by force of circumstances, somewhat of the nature of a specialist. He thought it would be an extremely good plan if a medical history sheet were the rule in every school, as it was in the majority of public schools. Very often, however, such sheets were not comprehensive enough. Dr. KENNETH WILSON, medical officer of Bryanston School, said that some school officers felt very acutely that they had not been chosen by the parents, and for that reason they were inclined to call in the consultant too often. Dr. Wilson added that he kept a book of "peculiar parents," who insisted on some rule or prohibition. He, too, had suffered from mothers. At one school where he was officer he wrote to a mother that her son should see an ophthalmologist; in reply he got four pages of abuse, with an insistence that the boy had perfect sight, but underneath the angry signature was a postscript: "My husband has just come in and seen your letter; he says, 'By all means have an ophthalmologist,' so please arrange!" Not liking to use medical terms in letters to parents, he wrote of a boy who had erythema nodosum that he had a rash down his shins which would undoubtedly clear up, but when the parents came, at the end of a fortnight, they declared that they had no idea it was erythema, and were angry, and took the boy away. Another boy had tinea cruris, and here he mentioned in a letter the technical term, whereupon the parents wrote complaining of the morals of the school, under the impression that the boy had venereal disease. Dr. L. R. LEMPRIERE of Haileybury complained of parents who sent drugs—even small medicine chests—with their boys to school.

Others who joined in the discussion were teachers and parents. The head mistress of a London girls' school pleaded for uniformity as to length of quarantine in infectious diseases. This lady added that during the twenty-five years she had been in charge of a combined day and boarding school there had only been one epidemic—of measles—and, apart from that occasion, never more than six pupils away at one time with the

same complaint. A father gave some amusing experiences of his search for a public school for his son. One well-known school had a well-equipped operating theatre and an enormous sanatorium, which "gave him the shivers"; another refused all information about epidemics, holding that parents were not competent to form an opinion. In one school he learned that cascara was administered as a routine measure twice a week to the younger boys; a school medical officer who spoke later considered this a very good thing. This same parent found the dietetics in many public schools "deplorable"; modern knowledge as to vitamins had not penetrated their ancient portals. The chairman of the Association of Preparatory Schools (Mr. J. E. MAITLAND) said that on visiting many public schools in America he had been impressed with the taking of medical histories, each history covering both sides of a quarto sheet. He proposed as an outcome of the discussion "a committee of health for schools," with representatives of masters, parents, and medical officers, but the suggestion was not taken up, and apparently the publication of the report of the discussion will be the only immediate result.

CORRESPONDENCE

Reform of the Medical Curriculum

SIR,—It may now, I think, fairly be assumed that the need for drastic changes in the medical curriculum is all but universally recognized. The recent history of this movement is of interest. Twelve years ago the General Medical Council, as a result of a special inquiry into medical education, issued recommendations on the subject which, if they had been given effect to, would have profoundly improved medical education and brought it much more into line with modern requirements. Little or no attention was paid to these recommendations by the various teaching bodies concerned. Since that date numerous references have been made to the subject in the columns of the leading medical journals, and by individual teachers who have interested themselves in reform of the curriculum, these references increasing in frequency and cogency in the past few years.

Coincidentally, for some years past the undergraduates of several medical schools, notably in Edinburgh and London, have expressed their views on the subject, indicating clearly their recognition of the need for reforms, adapted to bring their teaching more into line with the modern requirements of future general practitioners. In the last three years the Students' Representative Council of Edinburgh University has interested itself especially in the matter, frequent open discussions on the subject having been held and resolutions passed. Further, if we may take, as is likely, the Edinburgh medical school as a guide, it is known that certainly more than 90 per cent. of the teachers are in complete agreement as to the need and urgency for radical changes, although the agreement at once disappears when individual subjects come up for consideration.

More recently the British Medical Association has completed, through a specially appointed Education Committee, a valuable preliminary report on the subject, which has been submitted to, and approved by, the large Representative Body of the Association. The subject is now beginning to receive the close attention of the public, and numerous references to it have recently appeared in the Press. To mention one only, a recent leading article in the *Times* said: "It may very well seem to outside observers that reforms ought to be carried further than most of the professional advocates seem anxious to go. . . . What seems to be needed is a representation of outlook upon the physician's office."

There are many who are asking what is to be the next move in this vitally important question. There is undoubtedly a widely felt and expressed feeling that, probably arising largely from the interdependence of the various teaching and examining bodies, the necessary great reforms are not likely to be attained without appropriate legislative action. I share this view. The preliminary report of the B.M.A. committee has been of immense value, and appears to be amply complete for its main purpose. What seems necessary now is some form of judicious compulsion to get the principles laid down in the report universally applied in practice. This can be done in such a way as to leave a reasonable amount of elasticity called for by local conditions and traditions.—I am, etc.,

Edinburgh, March 10th.

CHALMERS WATSON, M.D.

Monilia in the Sputum

SIR,—The investigation reported by Dr. Bertram H. Jones in the *Journal* of March 3rd (p. 368) seems to afford a complete answer to those who attach undue significance to the finding of monilia in sputum. The publication has induced me to abandon, as no longer necessary, a desultory investigation designed to show the frequency of this finding; perhaps I may report here the results obtained hitherto—namely, that of eighty-four unselected specimens of sputum monilia could be demonstrated by cultural methods, usually only in small numbers, in fifty-three. Of these fifty-three strains forty fermented maltose, a property which G. K. Stone and I have shown (*Journ. Path. and Bact.*; 1931, xxxiv, 429) to correspond with pathogenicity for the rabbit, and to be characteristic of a serologically homogeneous group which it appears correct to designate *Monilia albicans*. There is ample evidence that this fungus is a common saprophyte and potential parasite in the mouth and throat, and the frequency of its mere presence in sputum, which must necessarily contain some proportion of admixed saliva, is therefore neither surprising nor significant.

In one direction, however, Dr. Jones's results are inconclusive. It is the contention of Dr. P. Janvrin Maret, who is stated to have suggested this investigation, that secondary infection with monilia is common in pulmonary tuberculosis. Only three of the cases reported by Dr. Jones were suffering from this disease, and one of them affords the solitary example in his whole series of monilia being found in the bronchial secretion itself. In my own series of sputa the presence of monilia was somewhat more frequent in specimens sent to be examined for tubercle bacilli than in those from, presumably, non-tuberculous cases, although the numbers concerned are so small that I wish neither to report them nor to suggest that they necessarily mean anything. Nevertheless a feeling of doubt remains, and the position really is that while Dr. Maret has not proved his contention, Dr. Jones, although clearly demonstrating an important source of possible error, has not disproved it.

While bronchoscopy, when it is feasible, is an ideal method of ascertaining the flora of the lower air passages, surely we need not altogether neglect the information obtainable by a more critical examination of ordinary sputum. In a fresh and otherwise suitable specimen monilia will be very few if they have been added to it in transit through the mouth; they may be very numerous if their origin is the ultimate source of the sputum itself. Dr. Maret's method of cultivation in a fluid medium would yield the same result in either case, whether, in fact, his inoculum contained only half a dozen monilia cells or a hundred thousand.

It is an elementary principle, which appears to have been neglected by some workers on this subject, that

the demonstration of a micro-organism which is not an obligatory parasite should be, at least roughly, quantitative. There is so much difference between the mere presence of a few monilia in culture from a sputum and their demonstration in profusion in direct films of fresh washed mucopus, a small fragment of which will yield thousands of colonies in primary culture on Sabouraud plates, that I even doubt whether Dr. Jones is justified in saying that "bronchomoniliasis cannot be diagnosed from the examination of the sputum alone." However that may be, I venture to commend more critical methods of sputum examination to those who believe that bronchomoniliasis is common, if only that they may thereby select cases for the more stringent type of investigation suggested by Dr. Jones.—I am, etc.,

LAWRENCE P. GARROD.

St. Bartholomew's Hospital, E.C.1, March 5th.

Influence of Oil Emulsions on Lethal Effects of Toxins

SIR,—I was much interested to read in your issue of March 10th an article by V. G. Walsh and A. C. Frazer on the effects of subcutaneous and intravenous injections of toxins combined with fine emulsions of oils. I have been investigating this problem during the past three years at this laboratory, and was pleased to learn that these two workers have obtained results which confirm my earlier findings. These findings were embodied in a thesis which was submitted by me to the Board of the Faculty of Medicine of this University eighteen months ago. As these two observers may not have seen this thesis, which is lodged in the University Library, or the abstract of the work which was published and circulated last year by the University Press,¹ I should be glad if you would allow me to publish a brief outline of the results obtained by me.

My experiments have been conducted on a large scale, and more than 1,500 animals have been used since the investigation was commenced with the late Professor W. E. Dixon three years ago. The majority of these animals were guinea-pigs, while a number of rabbits and cats were used also.

The object of the investigation was to determine whether oils and fats have any modifying influence upon the action of bacterial toxins. Oils and fats derived from vegetable, mineral, and animal sources were used, and those selected as being the most suitable were olive oil, liquid paraffin, and the cream of cow's milk. Their influence upon the lethal effects produced by the toxins of *B. diphtheriae*, *B. tetani*, *Cl. welchii*, and the *Vibrio septique* were studied. The oils and fats were mixed with aqueous solutions of lethal doses of the toxins so as to form emulsions, which were injected subcutaneously into animals.

The results of this investigation have shown that olive oil and liquid paraffin emulsions are able to protect animals against the lethal effects of 24 M.L.D. of these toxins; this was the experimental limit of the toxins used, but it is conceivable that larger doses of the toxins could be tolerated by the animals if given in this manner. The protection afforded by these emulsions is proportional to the fineness of the emulsion. Coarse emulsions afforded no protection against the lethal effects of these toxins. The addition of a binding agent, such as gum acacia, to the emulsions renders the protection more secure by making the emulsion more permanent. Unstable emulsions afford no protection whatever. I have also established that these toxins have a greater solubility or affinity for water than for the oil, even when they are mixed in the form of an emulsion.

The cream from cow's milk was found to afford no protection whatever against lethal doses of these toxins, even when

¹ Abstracts of Dissertations Approved for the Ph.D., M.Sc., and M.Litt. Degrees in the University of Cambridge. 1932-3. Cambridge University Press.

only 1.5 M.L.D. were used. My results have definitely shown that the oil of these toxin-oil emulsions is very slowly absorbed from the tissues after subcutaneous injection, accompanied by a slow liberation of the toxin. The serum of such animals when injected into other animals has been shown to protect against 2.5 and 3.5 M.L.D. of the specific toxin used. Further, it has been shown that a definite active immunity due to antitoxin formation can be produced by the injection of these toxin emulsions into animals. Such animals, after six weekly subcutaneous injections, can withstand 2 and 3 M.L.D. of the toxin used in the original emulsion.

I am at present improving this method with a view to applying it in clinical medicine for the production of active immunity against infectious diseases. I might add, in conclusion, that a short paper embodying these later results has been accepted for publication in the *Journal*.—I am, etc.,

G. NORMAN MYERS.

A Milk Ration for Children

SIR,—The *Times* of March 5th publishes a letter from Sir E. Graham-Little, in which he gives figures to show that certified milk is not safe. The letter does not say where the figures come from, nor where the samples were collected, and ends with this sentence: "The potentialities of mischief with a raw milk inferior to these grades [that is, Certified and Grade A (T.T.)] would therefore be even greater than the milk with which the experiment dealt." This suggestion that certified milk is little better than the ordinary ungraded filth is simply monstrous. Certified milk of extremely good quality can be produced, and is produced, and Sir E. Graham-Little's figures are no more than evidence of the shockingly slack supervision by the Ministry, which I brought to his notice some time ago. There is no reason why perfectly safe certified milk should not be produced in all parts of the country, and I would put the following points to Sir E. Graham-Little:

1. If he is not satisfied as to the safety of certified milk, what objection has he to my suggestion that the producer of certified milk should be allowed to pasteurize his milk?

2. If he prefers to damn certified milk until the producers, and their tubercle-free herds, are driven out of business, how does he propose to set about building up healthy herds again? Ordinary pasteurized milk will not do it. London has had pasteurized milk for many years and the herds supplying this milk are as diseased as ever.

3. Sir E. Graham-Little objects to certified milk for State-aided schools on the ground that it is too expensive. I venture to suggest that it is the duty of the medical authorities to prescribe what is best, regardless of cost; if the education authorities choose to buy pasteurized milk from diseased herds because it is cheap that is their responsibility. It is the clear duty of the Ministry of Health to provide a milk which everyone can recommend; the ordinary raw milk is out of the question; Sir E. Graham-Little refuses to recommend raw certified milk. I (for one) refuse to recommend the ordinary pasteurized milk from diseased herds. What is the objection to making pasteurized certified milk available?—I am, etc.,

Wetherby, March 5th

R. L. KITCHING.

SIR,—In the explanatory letter of Miss Marjorie E. Green in your issue of March 3rd (p. 402), in relation to your leader on the subject (February 24th, p. 339), it is stated that the term "fresh milk" was used simply to exclude dried and tinned milk. This statement is liable to be interpreted that, in the opinion of the committee,

milk powder and evaporated milk are unsuitable foods for children, and it cannot be allowed to pass unchallenged.

There is no need for the writer to stress the danger of raw milk as a carrier of disease—so admirably summed up in your leader—but the dietetic aspects may be considered so far as milk powder is concerned. Dame Janet Campbell, late of the Ministry of Health, in her report on infant mortality, after adverting to the dangers of raw milk, states:

"This difficulty is met by the distribution of large quantities of dried milk . . . this milk is of good quality and content, and its use for artificially fed infants has not only improved nutrition but has also directly prevented much gastro-intestinal disease which is so often caused by impure or stale milk."

Recent tests in supplementary milk rations for children carried out at the Princess Beatrice Centre, Fulham, and the Augusta Johnson Social Centre, Camberwell, extending over four months on sixty children, in which pasteurized milk was used in one group and roller milk powder in another, there was no difference in the gain of weight between the two milk groups over the control group. This gain equalled an increase of thirteen ounces over the increase in weight in the control group. Milk powder is being used in hundreds of schools as the basis of the mid-morning ration in the form of chocolate milk, etc., served hot with the most satisfactory results, and it is being used in preference to raw milk in hundreds of infant welfare centres and in the infant departments of our hospitals. In my contribution to this problem in the *Journal* of June 11th, 1932, I pointed out that, especially in the case of roller dried milk, an important dietetic advantage was secured in the feeding of children, inasmuch as the rennin coagulum of the reconstituted milk was of a flocculent nature, presenting a large surface for peptonizing action, in contradistinction to the solid curd of raw milk—a matter of supreme physiological importance in child dietary. In addition the powder is sterile to pathogenic flora, and the loss of vitamin in the powdering process, if any, is negligible.—I am, etc.,

East Dulwich, March 5th.

JOHN CAMPBELL, Ph.D.

Hypochondriasis

SIR,—May I thank Dr. Robert Hutchison for his excellent and timely paper on hypochondriasis in your issue of March 3rd (p. 365)? This paper should be reprinted, with suitable amendments, in every newspaper in the country, and should be learned by memory by the medical officers of the Ministry of Health and the Department of Health for Scotland.

However, I wish to refer, mainly, to the implications of that section of the paper dealing with the modern woman's mental attitude towards labour and her capacity to carry it through. In my opinion woman is becoming more unfitted (using this term in its broadest sense) to carry through an unaided labour.

What factors are at work to produce this result? First, the trend of civilization, especially since the later years of the war. This is a factor on which medical practice can have little effect. Secondly, the two points made by Dr. Hutchison: propaganda on behalf of the reduction of puerperal morbidity and mortality has reached the public in unsuitable form and out of proportion; also misdirected ante-natal work is fostering fear, which becomes intensified until labour is reached. For these factors the section of the profession concerned may be blamed. Thirdly, the overuse of some form of anaesthesia during labour. We have lay schemes whose object is to provide every woman in labour with anaesthesia. We have a scheme for anaesthesia by chloroform bombs to be given to every woman in labour in a large London hospital, with a

suggestion that ultimately every midwife in the country might use the bombs at will. We had the "twilight sleep" vogue, which certain medical opinion is bent on converting to a "gas-and-oxygen" vogue. Basal narcotics are being introduced in labour. We are apparently bent on teaching modern woman that interference in some form is indispensable in labour; and therefore, in her mental attitude, fear is once more encouraged. The ultimate outcome would seem to be a race of women—mentally incapable of carrying through labour unaided, and at a later stage physically incapable also.

No woman—in fact, no human being—is to be so admired as the woman who enters her first labour determined to make the best use of her physical powers, and completes her primary function with bravery, fortitude, and endurance. A correct mental attitude can shorten a woman's labour by hours, and save her a corresponding time of pain. It behoves every medical practitioner, therefore, by preparing his patient's mind during properly directed ante-natal care, to secure the undoubted benefit of that correct mental attitude, whenever possible. In this connexion the question arises as to the best place to conduct a labour. It is possible for the practitioner, by interpreting each patient's mental make-up, to know whether she will be a suitable case for domiciliary confinement, or whether the steadying influence of all-round competency, which should be present in the nursing staff of all types of institution undertaking midwifery, will be of assistance to the patient's mind.

The same problem emerges in the correspondence at present taking place in your columns over the pre-medication of operation cases. Dr. Hutchison is of the opinion that such considerations are of national importance, and the profession, at least, could mend its ways without revolutionary changes.—I am, etc.,

Kilmarnock, March 4th.

JAMES W. HAMILTON.

Tonsillectomy: Complete or Partial?

SIR,—In his letter in your issue of March 3rd (p. 406) Dr. Freer asks if diseased tonsils should be completely or partially removed. The overwhelming majority of laryngologists will, I feel sure, agree that they should be completely removed. We are speaking of diseased, not simple hypertrophied, tonsils. He implies, however, that complete removal can be achieved only by the dissection method, as he states "it would seem that the only rational procedure is complete removal by dissection, whereas partial removal by the guillotine only is wholly illogical, inadequate, and of questionable usefulness." This is not correct. Tonsils of the young can be perfectly enucleated by the guillotine, by the Whillis-Sluder method. It requires accurate technique, good "hands," and long practice to achieve skill with the guillotine. The art of dissecting tonsils is much more rapidly acquired. One has to do hundreds of tonsils by the guillotine before one becomes really proficient. Indeed, some never succeed in acquiring the art. Like hitting a golf ball, a certain knack is required as well as practice. It looks easy, but it is not so easy as it looks.

For the above reasons it follows that a good deal of imperfect work is done with the guillotine. This has given it a bad name. Indeed, I really think that the use of the guillotine is becoming a lost art! At the throat hospital where I learned my work some of the staff were adepts in its use. Now I am told the staff are all "dissectors," and yet in children the guillotine should give a perfect enucleation with less trauma and a lessened anaesthetic risk. For adults removal by dissection is the more reliable method.—I am, etc.,

Guildford, March 5th.

T. B. JOXSON, M.D., B.Ch.

Duties of the Medical Witness

SIR,—The writer of the article on "Duties of the Medical Witness," in your issue of March 3rd (p. 407), says: "An expert witness, in order to amplify his opinion, may quote from books of admitted authority." In a recent case in the High Court the judge refused to allow me to quote from an official volume of statistics, compiled in a Government Department and published by the Stationery Office. A medical witness should rarely wish to quote from a book, but in every case the question of admissibility is one for the judge to determine. It is not clear what the writer means by "admitted authority" in the above statement.

With regard to the advice not to use technical terms, this may easily be carried too far by medical witnesses. The popular word should only be used when it is the exact equivalent of the medical term, and then, as a rule, they are both equally well known. To paraphrase or use the nearest word for a medical term, such as "oedema" or "synovial membrane," for which there is no popular equivalent, is often to introduce an element of inaccuracy, which counsel will be quick to take advantage of. The best plan is to use the technical term, and then explain it, if necessary. Ambiguity may also occur. I remember a case in which a medical witness, following the advice given in certain books, spoke of "the lining membrane of the intestine," meaning the peritoneum, but was understood by counsel to refer to the mucous membrane, and there was considerable confusion in the court before the misunderstanding was cleared up.

In saying "He may be called in to a patient who dies in such circumstances that he cannot see his way to signing the death certificate" (for example, where the patient is suffering from injuries which may be due to violence or to an attempt at criminal abortion) . . . the writer of the article has evidently overlooked the provisions of the Births and Deaths Registration Act, 1926, which require a certificate to be given in every case, whether death was due to violence or not.—I am, etc.,

The Medical School, Charing Cross
Hospital, March 5th.

W. A. BREND.

Legal Ownership of X-Ray Films

SIR,—Dr. Swarbrick's criticism (March 10th, p. 459), coming from a medical man with practical experience of the customs governing the use of x-ray films in his Dominion, are most interesting. I fully sympathize with the slight degree of irritation which he expresses, for the legal attitude towards professional matters is apt to appear tiresome and somewhat unreal to practical men. There is little doubt, however, that any dispute would be largely settled on the custom which was proved to exist, and it is probable that he would have less dissatisfaction with the decision in an actual case than he has with my necessarily tentative generalizations.

The general practitioner faced with an action for negligence should have no difficulty in putting the x-ray films in evidence, for he would only have to serve a subpoena on the radiologist. The evidence of the radiologist would, in fact, be essential to prove the films. If he wished, as a general rule, to safeguard himself in every case he undertook, his best course would, I suggest, be to ask the radiologist for prints in order that he might file them with the records of the case. It is one thing to claim the legal ownership of a film and quite another thing to have the right to put it in evidence. The general practitioner's usual defence would, however, be to produce the radiologist's report, and say that, after himself seeing the films, he had agreed with, and acted upon, the opinion of the specialist, which he had every right to do. It is not part of the general

practitioner's duty to interpret films with the same skill as the radiologist.

I still do not think that there is a contract between the general practitioner and the radiologist as to the nature of the x-ray photograph to be taken. If the x-ray examination is done unsatisfactorily the patient can succeed against the radiologist and/or the general practitioner if either has been guilty of negligence. He can sue for breach of an implied contract to take care, for he is giving consideration in the shape of a fee. It is quite true that the use of experience and superior knowledge may be valuable consideration, but the general practitioner is giving this consideration to the patient and not to the radiologist, and therefore makes no contract with the radiologist. Perhaps your correspondent, brought up in a Dominion governed by Roman-Dutch law, does not quite appreciate the supreme importance of consideration in a valid English contract. The doctrine is, I believe, peculiar to the English common law. It may be that in South Africa the law would recognize a *justa causa* sufficient to constitute a valid contract between the two doctors, but that is not within my scope.

On the facts, I do not think that the radiologist can possibly be the agent of the general practitioner; he is not acting on the practitioner's instructions, but only giving his advice as an independent colleague. I cannot see anything absurd in the suggestion that the general practitioner cannot claim of his own right to see the film, because I am dealing purely with legal and not with ethical rights. I have, however, suggested elsewhere in the article that the patient, as the contracting party, certainly has the right to demand that his agent, the general practitioner, shall see the film, and the patient's legal right provides a basis for the practitioner's customary right.—I am, etc.,

March 11th

THE WRITER OF THE ARTICLE.

Fungus Infections of the Skin

SIR,—With reference to the discussion on fungus infections of the skin, reported in your issue of March 10th (p. 450), I am reported to have said, "he himself had found iodox ointment useful, but it left a disagreeable stain." I did say I had found iodox ointment useful. I went on to state that 1 per cent. gentian violet was another remedy I had tried, but it left a disagreeable stain. I do not consider that iodox ointment is disagreeable in any way, and I shall be glad if you will kindly make this correction.—I am, etc.,

London, W 1, March 9th.

P. O. ELLISON.

Ovulation and Menstruation

SIR.—I have been interested in the cases of intermenstrual bleeding to which Dr. Annie M. Hain refers in the *Journal* of March 10th (p. 454), and I reported eleven cases of this kind in 1929. If sections are made through the endometrium and myometrium of the uterus of women in the child-bearing period of life, it is not uncommon to find intense hyperaemia of the endometrium. Often large interstitial haemorrhages are formed in the functional layer, and in cases of intermenstrual bleeding of the type to which Dr. Hain refers it will be found that the bleeding is caused by oozing of the blood from the endometrium by a process which is different in its histology from that found in the menstruating uterus. The haemorrhages are not artefacts, for one can frequently find evidence of past haemorrhages in the form of connective-tissue cells engorged with blood pigment. These haemorrhages into the functional layer of the endometrium are encountered fairly frequently,

although they do not always give rise to bleeding from the uterus. The haemorrhages may be found quite early in the cycle, a few days after the end of menstruation. I do not think that the haemorrhages can be regarded as being restricted to the time of ovulation, for they can be demonstrated both before and when secretory hypertrophy is established.—I am, etc.,

London, W.1, March 12th.

WILFRED SHAW.

Hereditary Scoliosis

SIR,—In your issue of February 24th there is an article by Dr. Hugh H. Garland on hereditary scoliosis. I am acquainted with a family of which several members, in at least two generations, have (but do not suffer from) this slight deformity. In two cases the original deformity was a slight shortness (or perhaps coxa vara) of the right leg, and the resulting scoliosis did not develop or was not apparent until the later teens. Has this sequence of events originated in a faulty habit of standing, with the body's weight mainly resting on one leg, at a time when the bone was still imperfectly calcified, or is it due to a hereditary shortness of one leg?—I am, etc.,

Dervock, co. Antrim, March 7th.

THOMAS MCKEE.

Medical Examination at the Police Station

SIR,—Dr. Spurgin has quite misunderstood the observations of Mr. Justice Rigby Swift. The learned judge stated that in his opinion it was improper that a doctor, called by a patient accused by the police of being under the influence of drink, should express to the police any opinion on the condition of his patient. This, I think, we should all agree is absolutely correct ethics. In the particular case to which the judge referred the doctor had given to the police an opinion that the patient who had sent for him was under the influence of alcohol. Later he was actually called by the police as a witness against his own patient. Mr. Justice Rigby Swift expressed the view that under such circumstances the doctor should not retain the fee paid by his patient. The doctor accepted the suggestion of the judge, and returned it.—I am, etc.,

Hove, March 11th

L. A. PARRY, F.R.C.S.

The Services

Mr. Cecil P. G. Wakeley, D.Sc., F.R.C.S., F.R.S.Ed., has been appointed consulting surgeon to the Royal Navy.

DEATHS IN THE SERVICES

Lieut.-Colonel James Francis Donegan, C.B., R.A.M.C. (ret.), died at Farnham, Hants, on March 8th, aged 70. He was born at Cork on March 29th, 1863, and was educated at Edinburgh, where he took the L.R.C.P. and S. in 1885. Entering the Army as surgeon on July 28th, 1886, he became lieutenant-colonel after twenty years' service, and retired on March 29th, 1918. He served in the Burmah campaigns in 1887-9 (medal with clasp), and in the Peshawar and Tuckoo expeditions in 1899-92 (clasp); in the North-West Frontier campaign of 1897-8 (medal with clasp); in the South African War, 1899-1902, including the defence of Ladysmith, operations in the Transvaal and Orange Free State, in the actions at Talana, Laing's Nek, Red Bank, Belfast, and Lydenburg, and in operations on the Zululand frontier of Natal in September and October, 1901 (mentioned in dispatches in the *London Gazette* of February 8th, 1901 Queen's medal with five clasps and King's medal with two clasps); and in the war of 1914-18 (mentioned in dispatches in the *London Gazette* of April 5th and July 13th, 1916, and C.B. in 1916). He was the author of *Camp Songs, Ractime, Military Poems for Recitation* (1912).

Medico-Legal

THE DUTIES OF THE MEDICAL WITNESS.—II

NOTES TAKEN AT THE TIME*

Sometimes the success or discomfiture of a medical witness is determined years before the case comes on and he enters the witness-box. If a witness brings with him the original notes he has taken at the time of the event of which he is speaking he may use them to refresh his memory, but he is not allowed to use any other kind of memorandum. For this reason medical men cannot be urged too strongly and too often to take notes, at the time, of any matter on which they are in the least likely to have to give evidence later. A medical witness is in a very strong position if he can say to cross-examining counsel: "This is what I wrote immediately the patient had gone."

In 1926, a Mr. W. S. Harnett brought an action against Dr. Fisher, who had certified him as a lunatic fourteen years before. Naturally Dr. Fisher could not remember any details of the occurrence, and he had most unfortunately omitted to keep any notes. The result was that when he was cross-examined by Mr. Harnett's counsel he could not remember a single one of the questions which he had put to Mr. Harnett, or the answers on which he had founded his opinion that the man was insane. It is possible that if he had been able to arm himself with notes taken at the time he might have defended himself successfully against the charge of negligence, instead of having heavy damages awarded against him—from which he was only saved by the operation of the Statute of Limitations.

This is an extreme case, but even if the medical man is not faced with an action for negligence he may undergo public humiliation and confusion if he has to rely on an unaided memory—particularly if he is misguided enough to overdraw on it.

PENALTIES AND PROTECTION

The medical witness may receive from the solicitors of the party calling him a "subpoena"—a writ issued by the officers of the court in which the action is to be tried. It calls upon him to attend a named court at a named time, and may direct him to bring with him certain named documents. It carries the authority of the Crown itself. A copy is "served" on the witness, usually by one of the clerks to the solicitors acting for the party calling him; the original must be shown to him at the same time. The writ must be accompanied by sufficient conduct money and expenses.† If he is appearing purely as an expert and he has made an agreement with the solicitors about the remuneration he is to receive, they may possibly not serve a subpoena on him, but merely notify him by letter of the place and time. Coroners do not call witnesses by subpoena, but by summons, or sometimes by a mere informal message.

As its name implies, a subpoena carries with it a penalty for disobedience. A witness who disobeys a subpoena may be fined or imprisoned for contempt of court; he may be made to pay on pain of imprisonment a statutory penalty of £10; and he is also liable to be sued for damages by the party calling him if the party has suffered loss through not having the benefit of his evidence. The court will only punish him if he has shown intentional defiance of authority, and so he may escape by showing good and sufficient excuse. Among the excuses with which witnesses have in the past placated injured justice have been that the witness was ill and unable to travel; *bona fide* and reasonable grounds for thinking that he would not be required; and that he did not receive a proper sum for expenses with his subpoena. The following excuses, on the other hand, have been unsuccessful: that the case was not called on; or that it was called on unexpectedly; or that the witness's evidence was not material. A civil action

against a witness who did not appear when properly summoned would be founded, not on defiance of the commands of the court, but on his negligence in not performing the duty which he owed to the party calling him. He would therefore have to show that he had not been negligent; but the court, in deciding the point, would probably apply to his excuse the same standards as it would apply if he were defending himself against the charge of wilful disobedience. A coroner has the power to fine a witness £5 for not obeying his summons.

On the other hand, a witness is given by law certain protection to enable him the better to discharge the duty he owes the public. For instance, the court has inherent power to prevent any abuse of its process, such as service of a subpoena when the case cannot be tried in the current sittings, or of a subpoena which requires the witness to produce a number of unnecessary documents, or entails great expense, or is not served *bona fide* to obtain relevant evidence. The best course for a medical man who considers himself aggrieved by a subpoena is to talk the matter over with a good solicitor and to see whether it is worth while applying to the court to have the subpoena set aside. A witness is protected from arrest on civil process—for example, for not paying rates or a judgement debt—for a reasonable time before and after he gives evidence. What is more important to him is that he need have no fear of an action being brought against him for anything he says in his capacity as a witness. Even if a witness's evidence is damaging to the reputation or interests of some other person he cannot be sued for damages, because evidence given in court is absolutely privileged. The same privilege covers the "proof" of evidence which the witness gives to the solicitors and the party for whom he is appearing, in order that they shall know what evidence he is prepared to give.

In the case of *Watson v. McEwan* (1905) a woman who wanted a separation from her husband called in Sir Patrick Watson, an Edinburgh consultant, to examine her, in order that when she brought her action she might summon him as a witness to support her statement that her husband's cruelty had broken down her health. He examined her in 1901, and found that she was pregnant, and in the habit of taking alcohol and morphine, and among the notes which he made at the time in his private notebook he wrote the following passage:

"Advised should be sent to a nursing home till after her confinement over, to wean her from morphine, and separate her and her husband, and also her own family, until after the birth of the child. This view not pleasing to patient nor to her father (who has married a second wife), and it seems they are all bent upon inducing premature labour, so as to free the patient from any permanent reminder of this marriage, and, if possible, arrange a separation."

He naturally told the woman's law agents (this was a Scottish case) that his evidence would be unfavourable to her. A year later, when she brought her action in the Court of Session, Sir Patrick was consulted by the law agents acting for her husband and asked to examine the wife, together with other medical men, on the husband's behalf. This he did, and reported the result to the husband's agents, and at the same time voluntarily gave them information about the examination which he had made a year before, at the request of the wife, and showed them his notes. He gave evidence at the action and read his notes in court. She lost her action, and in 1904 sued Sir Patrick for (a) breach of confidence, and (b) defamation, asking for £2,500 damages on each head. The Court of Session, in deciding which of the issues she raised should be tried, disallowed those which dealt with Sir Patrick's evidence in the box on the ground that it was protected by absolute privilege. They also disallowed the issue that Sir Patrick had committed a breach of confidence in disclosing the information to the husband's legal advisers, but allowed the issue that in doing so he had slandered the wife. Sir Patrick appealed to the House of Lords. Lord Halsbury, the Lord Chancellor, said in his judgement: "It appears to me that the privilege which surrounds the evidence actually given in a court of justice necessarily involves the same privilege in the case of making a statement to a solicitor." If, he pointed out, an aggrieved person, though he could not bring an action on evidence given in the witness-box, could bring it for what the witness told the solicitor beforehand, he was going to say in the witness-box, the object for which the privilege existed would be gone, and no witness would ever give any information to solicitors.

* The first of this series of five articles appeared in the *Journal* of March 3rd (p. 407).

† *British Medical Journal*, 1933, ii, 513.

The public policy which makes the protection of witnesses necessary for the administration of justice must necessarily involve that which is a step towards, and part of, the administration of justice—the preliminary examination of witnesses to find out what they can prove. After all, if the witness lies in the box he can be prosecuted for perjury, and if he merely lies to the solicitor and his evidence does not get as far as the box, it does not much matter to anyone. The House of Lords therefore allowed the appeal with costs.

WHEN HEARSAY IS EVIDENCE

The law governing what evidence may be admitted and what may not is very long and complicated. The medical witness need know very little of it, since the question is one for the judge and counsel to thrash out. The doctor's task is to answer the questions which are put to him. If he observes the ordinary rule that hearsay is not evidence, he may help to save a little of the time of the court, but speedy correction will not be lacking if he infringes it. Nevertheless, there are a few fairly important classes of hearsay evidence which especially concern the doctor. One of these exceptions to the rule about hearsay is a statement made by a person about his bodily or mental feelings or condition, or state of health, if at the time the statement was made the feelings or condition were material to some issue in the proceedings. A doctor, or any other witness, may give evidence of such a statement to prove the facts set out in the statement. It does not matter whether or not the person against whose interests this evidence is given was present when the statement was made.

In *Aveson v. Lord Kinnaird* (1895) Aveson insured his wife's life. The medical man who examined her for the company found her a good life, and her husband warranted her to be in good health. She died shortly afterwards from the effects of immoderate drinking, and the insurance company refused to pay. The husband brought an action, and the company called evidence that soon after the medical examination she had complained to a neighbour that she had been poorly when she had gone to be examined and had not been fit to go, and that she was afraid that she would not live till the policy was returned. On this evidence the jury found that the husband had given a false warranty. The husband appealed on the ground that this evidence was improperly admitted, but the Court of King's Bench held that it was perfectly admissible.

Evidence such as this is obviously much more valuable if the doctor can bring the notes he made at the time in order to refresh his memory. He may not, however, read a letter written to him by a patient detailing his symptoms, and he can only tell the court how the patient described the actual symptoms he was feeling at the time. The patient may have told a lengthy narrative describing how the symptoms were caused, but the doctor cannot repeat this in evidence.

Dying Declarations

Another variety of hearsay evidence which the courts will sometimes admit is the dying declaration. When a doctor attends a patient whom he suspects or knows to have suffered from the wrongful act of another, he should bear in mind the possibility of the patient's making a declaration which may later become important if the offender is put on trial. The most likely instance is a case of criminal abortion which has gone wrong, and in which the doctor is called in too late to save the woman's life. She may make a statement about the acts which led to her death, and the doctor may consider it his duty as a citizen to take all steps to ensure that this statement is available as evidence if the offender is brought to trial. As it will not in any event be admissible if the patient lives, the question of professional confidence does not arise. If there is time, and he decides to act, he should ask a justice of the peace to come and take the statement, but it may be necessary for him to take it himself.

The first essential is that the patient shall be in settled, hopeless expectation of death. The theory is that the sense of approaching death is calculated to produce a sentiment of responsibility equal to that which a religious and conscientious man feels when required to make a

statement on oath. The doctor should take down her statement in writing, preferably before witnesses, and she should sign it if she is able to do so. Neither the writing, nor the witnesses, nor the signature are necessary; they will, of course, make the statement much more credible, but it must contain some expression of her knowledge that she cannot hope to live.

For instance, in *Rex v. Abbott* (1903) a woman who had taken nitric acid constantly repeated the words "I'm dying!" She did die in about twelve hours, and her husband, who had also taken the acid, but recovered, was charged with murder as the survivor in a "suicide pact." Mr. Justice Kennedy would not admit the declaration, even though the evidence that she had abandoned hope was very strong. He considered that the repetition made the evidence weaker, suggesting that the ejaculation referred to the pain rather than the fixed and settled belief in impending death.

In *Rex v. Goddard* (1882), however, where a woman said "I'm dying; look to my children," her statement was admitted by Mr. Justice Hawkins after consulting Lord Justice Baggallay. But in *Rex v. Jenkins* the woman, when her declaration was read over to her containing the words "with the fear of death before me," asked the clerk to put in the words "at present." These words prevented her statement from being received in evidence, as they showed that her despair was qualified and not absolute.

In *Rex v. Whitmarsh* (1898) a woman made a statement before she had lost hope, and afterwards, when really in fear of death and without hope, acknowledged it as true. Mr. Justice Darling would not admit it because he was unwilling to extend the doctrine of the admissibility of dying declarations in any way. Nevertheless, he admitted a statement which had been compiled by a metropolitan magistrate from extracts from this first statement, and had been read over to the woman and signed by her as correct. It was headed: "Having the fear of death before me, and being without hope of recovery."

In all the reported cases on whether a dying declaration was admissible, the injured person died (or the declaration would not have been admissible, whatever its form). In all of them the indications that hope had been abandoned were very strong. Yet so strict are the judges in interpreting this rule that they have rejected these statements whenever there was the slightest suggestion that the deceased had not definitely abandoned hope. If the doctor is ever responsible for recording a dying declaration, he must see that there is no hope, that the victim knows it, and that she says so clearly in her statement. A safe formula is: "Having the fear of death before me, and being without hope of recovery." When a dying declaration is otherwise admissible, it is not invalidated if the victim afterwards entertains hope before she dies.

For a full discussion of the controversy on the doctor's duty in this situation readers are referred to *Taylor's Medical Jurisprudence*, vol. i, p. 48.

(To be continued)

The annual report for 1932-3 of Livingstone College, Leyton, the medical training centre for missionaries, reveals that after a falling off in the number of students in recent years, the present session shows a larger number of entries, and that there is satisfactory promise as regards future ones. The value of this training is illustrated by citations from letters, and by reports rendered at the annual meeting held last June. There was a deficit of £143 on the year's working; in the previous twelve months the deficit was £346. This loss of income is attributable to a reduction in the fees payable by students by about 15 per cent., and partly by the fall in the number of students. During the last forty years Livingstone College has received 1,343 students, and the need of such a source of sound training for the relief of bodily disabilities has been abundantly demonstrated. At the annual meeting the value of this education was emphasized by the Archbishop of York, who urged that at least thirty students should be sent there each year to take the full course, as well as others for the shorter periods of training. The principal centre of clinical work for students is the medical mission at St. James the Less, Bethnal Green, and very useful practical assistance has been given by the Poplar, Connaught, Mildmay Mission, and Seamen's Hospitals.

Obituary

J. L. BIRLEY, M.D., F.R.C.P.

Physician to St. Thomas's Hospital

By the death, on March 6th, of James Leatham Birley, at the early age of 49 years, the profession has lost a member of outstanding ability and striking personality.

Born on July 12th, 1884, he was educated at Winchester and at University College, Oxford, where he gained first-class honours in the final school of physiology. After qualifying from St. Thomas's Hospital he held the post of house-physician at his own hospital and at the National Hospital for Nervous Diseases, Queen Square, returning later to St. Thomas's as resident assistant physician. During the following three years the war claimed all his time and energies, and from the first great battle of the Somme until the end of the fighting he was largely concerned with the development of the medical service of the Royal Air Force. His valuable work in that sphere was quickly recognized, and he rose to the position of its chief medical officer in France, with the rank of lieutenant-colonel, and, after his return to civil life, became its consulting physician, a post he retained

until his death. In 1919 Birley was elected a Fellow of the Royal College of Physicians, and in 1920 he gave the Goulstonian Lectures, choosing as his subject "The Principles of Medical Science as Applied to Military Aviation." The remainder of his life was chiefly devoted his work on the staff of St. Thomas's Hospital, and with the exception of a few years, when he was assistant physician to the National Hospital in Queen Square, he held no other hospital appointment.

Birley's great interest lay in neurology and in psychological medicine. He was one of the first honorary secretaries of the Council of Mental Hygiene, the excellence of his work in that capacity being greatly enhanced by his sane and critical outlook on the difficult problems with which the Council was confronted in its early days. It is to be regretted that—owing partly to his constitution, which was far from robust, and partly to his dislike of rushing into print unless he had something of worth to contribute to the fund of common knowledge—his literary efforts were not more numerous, because he had the gift of expressing his thoughts both clearly and attractively. His Goulstonian Lectures afford ample evidence of his powers of exposition, and they must remain for a long time—it is to be hoped for ever—one of the best attempts to describe the reactions, physiological, physical, and psychological, of the normal individual to the stress and strain of an entirely strange and exacting environment. In particular, his shrewd analysis of the factors which lead to a breakdown of human efficiency, and the clinical picture of these factors at work on active service, form an invaluable guide to those in authority should the necessity for fighting in the air again arise. Birley's physiological training at Oxford profoundly influenced his outlook on medicine, and, combined with his sympathetic understanding of a patient's individuality and his transparent honesty of purpose, made him, at an unusually early age, a consultant whose opinion was eagerly sought and respected by the profession, especially in the field of neurology.

In no gathering could Birley be overlooked. His height, his athletic figure, and fine ascetic features never failed to arrest attention, and closer acquaintance with the man revealed keen intelligence, wide culture, and an unusual capacity for clear thinking and quick decision. In his too infrequent hours of leisure he was a delightful and exhilarating companion; his personal charm, his appreciation of the humorous aspects of life, his infectious laugh, and the absence of any kind of affectation, gave him the immediate and lasting friendship of children, while, if adults might at first be a little alarmed by his penetrating directness of manner, the genial warmth of human kindness which lay beneath soon dispelled their fears. His accomplishments and hobbies covered a wide field. He excelled at the piano and at the billiard table. His intimate knowledge of the turf and of cricket, and his intense love of nature, more especially of birds, gave his holidays a full measure of interest and recreation.

A short but rich life, conscientiously spent, and blessed with the crowning glory of a supremely happy marriage. His wife, Margaret Edith, elder daughter of Mr. W. A. Tennant, with two sons and a daughter, survive him. To them, in their loss, is assured the deep sympathy of a large circle of mourning friends within and without the profession which James Birley adorned.

E. F. B.

WILLIAM DARLEY-HARTLEY, M.D., M.R.C.P.

Emeritus Editor of the Journal of the Medical Association of South Africa (J.M.A.)

We have to record with regret the death of Dr. W. Darley-Hartley of Rondebosch, Cape Province, in his eightieth year, after a life of devoted service to South Africa and to the British Medical Association.

Born in Sheffield in 1854, William Darley-Hartley received his medical education at Guy's Hospital. He obtained the diploma M.R.C.S. in 1878, and the L.R.C.P. Ed. in the following year. A house appointment at Guy's Hospital followed his qualification, but the outbreak of the Zulu War led to a change in his plans, for he was offered, and accepted, a post as civil surgeon in the force which was hurried to South Africa. A year later hostilities ended for the time with the overthrow of Cetewayo, and Dr. Darley-Hartley decided to settle in South Africa. He built up a good practice in East London, and then accepted the post of district surgeon at Cathcart. His previous experience resulted in his obtaining also a commission as captain in the Frontier Mounted Rifles. Four years later he returned to East London, but there was little likelihood of a long sojourn, for the Boer colonists were pushing out first from the Orange Free State, and then from the Transvaal, into the territory of the Bechuanas; the inevitable war ensued, and Dr. Darley-Hartley once more ceased to be a civilian practitioner. There followed the exciting but sadly unsettling times when Cecil Rhodes and others were vigorously engaged in composing disputes, withstanding native risings, securing safety in new territories, and gradually establishing the foundations of what was to be eventually a civilized country under white control. In all these varied activities of a transitional period Dr. Darley-Hartley took part.

This early experience of pioneering had its inevitable influence on the character of a man who had always been of resolute purpose. Moreover, he had gained a deep affection for South Africa, and was always ready to take what opportunities offered to advance her interests. He visited England in 1898 for a short time, during which he obtained the M.R.C.P. and graduated M.D. at Durham. He returned to Capetown to restart his medical life as a consultant physician, but the continuance of the unsettled national conditions prevented him from fully

developing this line of work, and the Boer War once more recalled him to the duties of a civil surgeon with the British forces, until peace was signed and his life took a new, but no less vigorous, turn. Elected to membership of the British Medical Association in 1895, Dr. Darley-Hartley had formed a clear view of what such an institution might be capable in South Africa. Already an experienced journalist, he determined to try to succeed where others had previously failed, and accordingly he founded the *South African Medical Record*, which was to be a mouthpiece of unfettered medical opinion. He inevitably encountered opposition, both to some of the views and also to the way in which they were expressed. Foes as well as friends multiplied, and his previous life had not been of a kind to soften his attitude in controversy. As a member of the Cape of Good Hope (Western) Branch Council in 1904, and the Cape Colony Medical Council, of which he was at one time president, he made his strength of purpose felt, and eventually in medical circles, as previously in the country as a whole, ways of making peace were found.

Reporting on his visit to South Africa in 1926 (*B.M.J. Supplement*, 1926, i, 234) the then Medical Secretary, Dr. Cox, described Dr. Darley-Hartley as one "who occupies in South Africa a position suggesting an unofficial combination of the Editor of the *B.M.J.* and the Medical Secretary." Thus, when 1926 was reached, and the Medical Association of South Africa came into being, the *South African Medical Record* was accepted as its official organ under the title of the *Journal of the Medical Association of South Africa (B.M.A.)*. After editing the paper in its new form for two years he retired, and was appointed emeritus editor. In the same year he headed the poll at the election of the new South Africa Medical Council. Further recognition of his outstanding merits followed in 1933, when he was awarded the gold medal of the Medical Association of South Africa (B.M.A.), and elected an honorary member. His latter days were spent in his home near Groote Schuur—once the abode of another who gave his heart to South Africa—and in the suburbs of Capetown, where he had in the end won his way through strife to peace and honour.

THE LATE DR. A. G. BARRS

Dr. C. H. CATTLE (consulting physician, Nottingham General Hospital) writes: In the notices of the late Dr. Barrs of Leeds in your issue of March 10th I do not see any reference to his very valuable paper in the *British Medical Journal* for May 10th, 1890, on "The Tuberculous Nature of So-called Simple Pleuritic Effusion." This view of pleurisy was at the time almost revolutionary. Text-books ascribed simple pleurisy to "cold," "idiopathic causes," "rheumatism," "blows on the chest," etc., but never mentioned tubercle as a cause of primary pleurisy. Dr. Douglas Powell had already raised the question whether some "simple pleurisies" might not be tuberculous. He was familiar with the fact, now so well established, that "simple pleurisy" was often followed by phthisis. Dr. Barrs frankly stated his disbelief in the influence of cold as a cause of disease: as our knowledge of microbic causes has increased, by so much have the fields of "cold" and "idiopathy" diminished. He examined the records of the Leeds General Infirmary for 1880-4, and found that twenty-one out of seventy-four cases of simple pleurisy resulted in death within five years from some other tuberculous affection. A recent modern textbook ascribes the majority of cases of pleurisy to the tubercle bacillus, allowing chill or injury as depressing and contributory causes. Dr. Barrs was one of the first in this country to give expression to this view of the origin of pleurisy, basing his opinion on careful observation, and has thus earned a place among the many great men who have added to our knowledge of tuberculosis.

We regret to announce the death on March 8th of Dr. WILLIAM WILKING STABB of Torquay. From Cambridge, where he graduated with honours in the Natural Sciences Tripos in 1887, he went to St. Thomas's Hospital, and obtained the M.B. and B.Ch. degrees in 1890, proceeding M.D. three years later. At St. Thomas's he won the Mead Medal for practical medicine, and served as resident house-physician. He then began general practice at Torquay, and at the age of 26 was appointed physician to St. Raphael's Convalescent Home, administered by the Clewer Sisterhood; he was also for many years medical officer to the St. Barnabas Home for Incurables. He had been a member of the British Medical Association for forty-three years. We have received from the Hon. Lady Leveson-Gower a tribute to Dr. Wilking Stabb's fatherly care of the patients at St. Raphael's Home, where he earned the devotion and gratitude of all. He worked assiduously with the various sisters superior who succeeded one another, and never failed in his skilful attendance and kindness to the patients. "In 1892," writes this correspondent, "I was a girl of 22 dying slowly from myxoedema, for which nothing could then be done. In the autumn of that year Dr. Stabb learned of raw sheep's thyroid as a cure, two women in Scotland having benefited through this discovery. Dr. Stabb, young as he was, absolutely inexperienced both as regards the illness and the cure, took that responsibility against the advice and warning of other doctors both in London and at Torquay—with the result that I recovered sight, hair, figure, speech, and movement, and lived to enjoy excellent health."

We regret to record the death of Dr. CHRISTOPHER THOMAS HELSHAM of Breckles on March 3rd, at the early age of 39. His medical education was somewhat interrupted by the war. He held a commission as surgeon probationer R.N., and was awarded the D.S.C. After studying at Newcastle and Guy's Hospital, he obtained the diplomas M.R.C.S., L.R.C.P. in 1919. His early appointments included house-surgeon at Guy's Hospital and the Norfolk and Norwich Hospital. Continuing to specialize in surgery, he settled at Breckles and was appointed surgeon to the local hospital. He was the author, in 1921, of an article in the *British Medical Journal* on a case of strangulated scrotal hernia with a volvulus of the small intestine in the inguinal canal. Dr. Hesham was a keen supporter of the British Medical Association. He was a Representative at the Annual Meeting at Bradford in 1924, and again at the Meeting at Nottingham in 1926, and had been chairman of the North Suffolk Division. He was also a member of the Norwich Medico-Chirurgical Society.

We regret to announce the death on March 7th, at the age of 78, of Dr. THOMAS GEORGE AINSLEY, at West Hartlepool, where he had resided for seventy years. Dr. Ainsley received the diploma of M.R.C.S. in 1877 and the degree of M.B. Durham in 1880, proceeding M.D. in 1887. Dr. Ainsley was a justice of the peace for the county borough of West Hartlepool, and consulting surgeon to the Hartlepool Hospital and Cameron Hospital, West Hartlepool. He had been a member of the British Medical Association for fifty years. By a sad coincidence his brother, Mr. F. W. Ainsley, died the same day.

The death is announced, on March 2nd, at the age of 68, of Dr. THOMAS STEELE of Ardmuir, Cadzow Street, Hamilton, N.B. A native of Faudhouse, Dr. Steele graduated M.B., C.M.Ed. in 1891. After practising for a short time in West Hartlepool he became assistant to Dr. Lennox and Crawford in Hamilton forty-two years ago, and later succeeded the latter as senior partner, retiring in 1933. He held the position of surgeon to the Lanarkshire County Police, medical officer to the Post Office, and certifying factory surgeon for the Hamilton

district. During the war Dr. Steele carried on the practices of several brother doctors in the district, and this arduous work, which was faithfully and cheerfully done, will always be gratefully remembered. A popular practitioner, Dr. Steele was also a keen sportsman, and held the captaincy of the Hamilton Golf Club for several years. He had been a member of the British Medical Association for forty years, and took a lively interest in the proceedings of the Lanarkshire Division.

By the death of Dr. W. M. SHUTTE on March 5th Weybridge has lost a much-loved doctor and friend, who had practised there for many years. He received his medical education at the University of Cambridge, where he graduated M.A. in 1898, and at St. George's Hospital, qualifying as M.R.C.S. and L.R.C.P. in 1904. At the outbreak of war he immediately joined the R.A.M.C. and served in England and France for the whole of its duration. After the cessation of hostilities he sat for some years on many of the Pensions Boards, but did not return to private practice, though he still continued to reside in Weybridge until the day of his death. He leaves behind a wife and family, and countless friends to mourn his loss.

Universities and Colleges

UNIVERSITY OF OXFORD

Schorstein Research Fellowship

The Board of the Faculty of Medicine will make an election to the Schorstein Research Fellowship in Medical Science in June, 1934, if a candidate of sufficient merit presents himself. The board has power, in special circumstances, to divide the fellowship into two studentships.

The fellowship, of the annual value of £200, will be tenable for two years from October 1st, 1934, in any of the medical departments at Oxford, under such regulations as the board may approve. Candidates must be graduate members of the University, holding a registrable medical qualification, and must be under 35 years of age on October 1st, 1934. Candidates must submit their applications to the dean of the Medical School, University Museum, not later than April 30th, 1934. Each candidate must submit evidence of age, testimonials (three copies) or names of referees, a statement of his career, and a statement of the department of medical science in which he proposes to research.

The Board of the Faculty of Medicine has granted leave to F. J. Sale, B.A., B.M. (Christ Church), to supplicate for the degree of Doctor of Medicine. The evidence submitted by the candidate was entitled "Auricular Fibrillation."

UNIVERSITY OF CAMBRIDGE

The Syndicate on Medical Courses and Examinations of the University has issued a second report dealing with the necessary changes of Ordinance so far as its previous recommendations concern degrees in medicine and surgery. The regulations proposed (*Cambridge University Reporter*, March 6th, p. 703) include all the recommendations dealt with in the Syndicate's amended report, which was approved on November 17th, 1933, and they deal also with certain minor points not previously considered.

Dr. E. B. Verney, F.R.C.P., formerly scholar of Downing and now Professor of Pharmacology in University College, London, has been appointed to the Sheild Readership in Pharmacology as from October 1st, 1934.

Sir Pendrill Varrier-Jones has been appointed to represent the University at the twentieth annual conference of the National Association for the Prevention of Tuberculosis, to be held in London in June.

F. M. Collins and D. M. Lewis have been approved for the degree of M.Chir. Kathleen Alice Muir has been approved for the degree of M.D.

At a congregation held on March 10th the following medical degrees were conferred:

M.D.—H. G. Oliver, G. S. W. Evans.
M.B., B.Chir.—J. T. W. Spiridion-Klisczewski, W. G. Gill,
G. L. Alcock.
M.B.—H. F. Green.
B.Chir.—P. T. Cooper.

UNIVERSITY OF SHEFFIELD

Dr. Edward Johnson Wayne has been appointed to the Chair of Pharmacology in succession to Professor Edward Mellanby. Dr. James Clark has been appointed Lecturer in Infectious Diseases.

The Council has appointed Professor G. A. Clark, Dean of the Faculty of Medicine, to represent the University at the celebration commemorating the one hundredth anniversary of the foundation of the Liverpool medical school on May 11th and 12th.

NATIONAL UNIVERSITY OF IRELAND

At a meeting of the Senate on March 8th, with Dr. Denis J. Coffey, Pro-Vice-Chancellor and President, University College, Dublin, in the chair, a resolution of congratulation to Dr. Coffey upon the signal honour recently conferred upon him by the President of the French Republic by including him amongst the Chevaliers of the Légion d'Honneur was unanimously adopted.

The Senate decided to award the M.D. degree to the following candidates upon the published works submitted by them: B. A. Coghlan and W. J. Roche of University College, Dublin.

The Senate decided that the prize in Irish historical research for 1933 should be awarded to Dr. Richard Hayes for his published work entitled, "Ireland and Irishmen in the French Revolution."

The following representatives were appointed: Dr. Denis J. Coffey to attend the centenary celebrations of the foundation of the medical school, University of Liverpool, in May; Professor John C. Saunders to attend the annual conference in London of the National Association for the Prevention of Tuberculosis.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Council Election

The secretary of the Royal College of Surgeons has sent out the usual announcement, which on this occasion states that on Thursday, July 5th, at 11 a.m., there will take place an election of four Fellows into the Council in the vacancies occasioned by the retirement in rotation of Mr. Ernest W. Hey Groves, Mr. G. Grey Turner, and Mr. Hugh Lett, and by the death of Mr. R. P. Rowlands.

A voting paper will be sent by post to each Fellow whose address is registered at the College on April 3rd. Fellows are requested to give notice without delay of any change of address, in order that voting papers may not be mis-sent.

Meeting of Council

A meeting of the Council was held on March 8th, with Sir Holburt Waring, the President, in the chair.

Mr. R. H. Burne, F.R.S., the Physiological Curator of the Museum, who is retiring from office, was presented with an address expressing the Council's appreciation of his services to the College during a period of forty-two years.

Licences in ¹/₂ Natal Surgery were granted to thirty-three candidates.

Diplomas in Ophthalmic Medicine and Surgery were granted, jointly with the Royal College of Physicians, to the following eighteen candidates:

H. W. Applin, Edith D. Bowie, W. G. Davidson, G. D. Gordon, H. G. Grieve, J. N. Jaswal, A. R. Khan, E. H. W. Lyle, P. H. Maal, W. B. E. McCrea, G. G. Patel, A. W. Patton, L. G. Scoular, I. Sherrie, K. H. Singh, Effie Slater, P. I. Tierney, R. L. H. Townsend.

BRITISH COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

The Council has elected to Honorary Fellowship Emeritus Professor Archibald Donald (Manchester), and Sir William Josiah Smyly (Dublin). The following Members have been admitted to the Fellowship: A. M. Claye (Leeds), D. Counts (Patna), J. Ellison (London), P. F. Gow (Calcutta), S. N. Hayes (Lahore), M. L. Treston (Rangoon).

The following have been awarded the Diploma of the College: W. N. Chisholm (Preston), V. H. J. Davies (Swansea), J. C. Hatrick (London), R. S. MacArthur (Stourport), Adali E. Platts-Mills (London), P. R. Thiagarajah (Ceylon), Gertrude Cuttle (Liverpool), A. S. Rajasingham (Ceylon), H. Richards (Cambridge), G. D. S. Briggs (London).

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At the monthly meeting of the Royal Faculty of Physicians and Surgeons of Glasgow, held on March 5th, the following were admitted Fellows: M. D. Black, W. Blyth, T. W. Buchan, W. A. Mackey, and G. McC. Wyburn.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The House of Commons this week discussed the Estimates for the Navy and Army. The Consultative Committee on the Army agreed that at an early opportunity Sir Francis Fremantle should speak on the correlation of the Medical Services in the Defence Forces.

The Mining Industry (Welfare Fund) Bill was considered on report and read a third time in the Commons on March 13th. On the same night the Rural Water Supplies Bill came up for third reading, having passed through committee on March 7th. The Offices Regulation Bill was down for second reading on March 16th.

In the House of Lords on March 13th the Shops Bill passed through committee. Amendments were made in the provisions for overtime. The Supply of Water in Bulk (No. 2) Bill was considered on report by the Lords.

On March 7th the Parliamentary Medical Committee and lay M.P.'s met Lord Moynihan and Lord Dawson of Penn. Lord Moynihan explained the Road Traffic Emergency Treatment Bill, which has been sent to the Commons from the Lords. As time is unlikely to be provided for this by the Government, the meeting, which was generally sympathetic with the objects of the Bill, agreed that a deputation from both Houses should be appointed to represent to the Minister of Transport the case of hospitals and medical practitioners for statutory compensation for treating motor accidents. Three suggestions were made in the discussion: a contribution of £100,000 annually from the Road Fund; a levy on motor licences; or a contribution from motor insurance. The Ministry of Transport was stated to be against all three. To serve on the deputation to the Minister the meeting selected Lord Moynihan, Lord Dawson, Colonel Moore, Sir Francis Acland, Sir Arnold Wilson, Dr. Salter, and Sir Francis Fremantle, to whom two or more lay peers would be added. Lord Dawson then explained the Contraceptives Bill, as amended in committee. The third reading of the Contraceptives Bill is set down in the House of Lords for March 20th.

The certificate issued by the Attorney-General on the Birmingham Joint Hospitals Bill is in its favour, but suggests minor amendments.

The Adoption of Children (Workmen's Compensation) Bill has been reported to the House of Commons with amendments from a Standing Committee.

Particulars of the slum clearance programmes submitted by local authorities in England and Wales were issued on March 13th as a White Paper. This shows that 266,851 houses are proposed for demolition during the five-year programme under the Slum Clearance Act, 1930, and that 285,189 new houses are to be built for the 1,240,000 persons dispossessed. The Government will, at a later date, introduce a Bill for a complementary policy on reconditioning houses. The peak of slum clearance is expected in 1936-7. The preliminary surveys have been made on the advice of medical officers of health.

Insurance Capitation Fee

Replying to Major Mills on March 8th, Sir HILTON YOUNG, Minister of Health, stated that the capitation fee payable to insurance doctors was, by agreement with the British Medical Association, reduced from 11s. to 9s. 6d. per insured person as from January 1st, 1922, and, after reference to a court of inquiry, from 9s. 6d. to 9s. from January 1st, 1924. The fee of 9s. was made subject to an economy deduction of 10 per cent. from October 1st, 1931. The amount of the saving effected by a reduction of the capitation fee depended on the number of insured persons entitled to medical benefit, which

varied from year to year. The saving accruing to the national health insurance funds of England and Wales in the first year of the first reduction was approximately £995,000, and the saving in the first year of the second reduction was approximately £342,000. The Exchequer proportion of these sums was approximately £221,000 and £76,000 respectively. The whole of the saving effected by the economy deduction of 10 per cent. accrued to the benefit of the Exchequer, and this saving in England and Wales in 1932 amounted approximately to £715,000. [The official report of a deputation to the Minister from the Insurance Acts Committee of the British Medical Association is printed in the Supplement this week at page 97.]

Milk for School Children

Mr. RAMSBOTHAM told Mr. Elliott, on March 8th, that the Board of Education, in approving proposals by local education authorities for the provision of milk to school children, urged the authority to make every effort to secure a supply of pasteurized or tuberculin-tested milk. Captain Heilgers asserted that it was difficult to obtain Grade A (T.T.) milk because "the medical profession has a preference for dirty milk pasteurized, and that preference has nearly killed the production of clean milk in this country." No answer was returned.

Sir F. FREMANTLE, on March 12th, asked the Minister of Agriculture whether, before approving any proposals submitted by the Milk Marketing Board for providing milk to schools at reduced rates, the Government would satisfy itself that such milk would be free from the risk of tuberculosis or other infections. Dr. ELLIOT replied that under present voluntary schemes the source of milk supplied to schools had to be approved either by the school medical officer or by the local medical officer of health. He had no doubt that the Milk Marketing Board would take note of existing procedure in framing the proposals which it would submit for approval, and he would bear the point in mind himself.

Mr. SHAKESPEARE, on March 12th, told Sir Arnold Wilson that the attention of the Minister of Health had been drawn to a report on causal factors in tuberculosis, published by the National Association for the Prevention of Tuberculosis. Sir Arnold Wilson asked if the Minister's expert advisers confirmed the view that the incidence of tuberculosis varied with the consumption of raw milk, "a shortage of which more than of any other foodstuff is a predisposing cause of tuberculosis." Mr. Shakespeare said the causal factors in tuberculosis were numerous and complex, including under-nourishment, but the Minister of Health was advised that the nutritive value obtained by the consumption of raw milk might be accompanied by some increase in the risk of infection by bovine tubercle bacilli unless suitable precautions were taken to ensure the safety of the milk.

Water Shortage: Government Action

Replying, on March 12th, to Mr. LEVY, Mr. SHAKESPEARE said that it was not proposed to give the regional advisory committees statutory powers to enable them to carry out schemes of regional water supply. The committees had been formed for advisory purposes only.

Replying to Sir J. LAMB, Mr. Shakespeare said that, so far, 475 rural district councils had replied to the recent circular on the shortage of water due to drought. Of these, 315 reported that their districts were not suffering from shortage; the remaining 160 reported shortage of varying degree. Where shortage was reported, with few exceptions special measures were being taken. Where the replies suggested that further action was required, a visit was made by an engineering inspector of the Ministry of Health. Additional engineering staff had been engaged to enable this to be done.

Payment of Midwives' Fees.—Sir HILTON YOUNG told Mr. D. G. Somerville, on March 8th, that cases had come to his notice in which midwives had complained of difficulty in obtaining payment of their fees. The choice of a midwife and the amount and payment of her fees were matters of private contract between the midwife and the person engaging

her services. Where the confinement was that of a woman entitled to maternity benefit the payment of the midwife's fee was ordinarily regarded as the first charge upon that benefit. He did not think that the introduction of amending legislation to protect the interests of the midwife in this respect would be justifiable.

Tuberculosis Death Rate.—Sir HILTON YOUNG told Captain J. MacAndrew, on March 8th, that, on the basis of the standardized death rates for all forms of tuberculosis annually published in the Registrar-General's Statistical Review, the 1932 mortality in England and Wales was approximately 56 per cent. of that in 1911 and 22½ per cent. only of the corresponding mortality of the quinquennium 1851-5. Comparable figures for European countries were not completely available, but it would appear that no less improvement had been experienced in certain other countries. The Minister informed Mr. A. Todd, on March 8th, that no further tests had been carried out by the Ministry of Health in connexion with the treatment for tuberculosis called *innecaloabo*.

Slaughter of Tuberculous Cattle.—Replying, on March 8th, to Dr. Howitt, Mr. ELLIOT said that, during eight years' operation of the Tuberculosis Order of 1925, up to September 30th, 1933, 141,220 tuberculous cattle were slaughtered by local authorities in Great Britain. Compensation paid amounted to £521,581.

Bovine Tuberculosis.—On March 13th Sir HILTON YOUNG, replying to Mr. Groves, said he was advised that there was proof that the cases of tuberculosis in which the bovine germ had been found were caused by that germ. The scientific proof of this would be found in the second Interim Report of the Royal Commission on Tuberculosis (Human and Bovine), Part I (Report), 1907, Cd. 3322.

Housing.—In reply to Mrs. Tate, on March 8th, Sir HILTON YOUNG said that, with the exception of London and of a few instances in which he was negotiating with the authorities concerned with a view to securing acceleration, the slum clearance programmes adopted by local authorities were for completion within five-years. The Minister told Mr. Mitchellson, on the same day, that the estimated number of houses in England and Wales per 1,000 of the population in September, 1933, was 245.8. The corresponding numbers at the censuses of 1911 and 1921 were 214.9 and 211.9 respectively. Mr. Shakespeare states that up to February 28th 2,083 areas had been declared by local authorities to be slum clearance areas.

Medical Officers Employed by Local Authorities.—On March 12th Mr. RAMSBOTHAM informed Sir Wm. Jenkins that in 1920-21 316 local education authorities in England and Wales employed 812 school medical and assistant medical officers; 235 authorities employed 420 school dentists; and 316 authorities employed 1,941 school nurses. In 1932-3 316 authorities employed 1,341 medical officers, equivalent to 659 whole-time officers; 312 authorities employed 774 dentists, equivalent to 555 whole-time dentists; and 316 authorities employed 5,630 nurses, equivalent to 2,243 whole-time nurses. In 1925-6 twenty-seven orthopaedic surgeons were directly employed by local education authorities; in 1932-3 the number was 125. Orthopaedic schemes were frequently operated by arrangements between local education authorities and orthopaedic hospitals. In those cases the orthopaedic surgeons were not directly employed by the authorities.

Drunkenness from Methylated Spirit.—Mr. HACKING, replying to Mr. McEntee on March 12th, said that in 1928 there were 446 convictions for drunkenness attributed to the drinking of methylated spirit in England and Wales, and 40 in the County of London. In 1929 there were 409 convictions in England and Wales and 39 in London. In 1930 the figures were: England and Wales, 476; London, 22; in 1931: England and Wales, 582; London, 24; in 1932: England and Wales, 596; London, 30. These figures included cases of persons who had been convicted on more than one occasion. Full particulars for 1933 were not yet available.

Notes in Brief

At the end of 1933 the number of persons in England and Wales in receipt of a pension under the Blind Persons Act, 1920, was 22,167.

Medical News

A meeting of the medical staffs of the London teaching hospitals, to consider the problem of London's hospital development, will be held at B.M.A. House, Tavistock Square, W.C., on Thursday next, March 22nd, at 5 p.m., with Lord Horder in the chair. The discussion will be opened by Dr. J. S. Fairbairn, Sir Crisp English, Mr. V. Zachary Cope, and Dr. Geoffrey Evans. It is hoped that there will be a full and representative attendance. A leaflet dealing particularly with the Hospital Policy of the British Medical Association as it concerns London has been prepared for the occasion by the officers of the Metropolitan Counties Branch.

The annual dinner of the Irish Medical Schools' and Graduates' Association will be held at Claridge's Hotel to-day (Saturday), March 17th, at 7.45 p.m. The guests of honour will be the Countess of Iveagh and Lieut.-General J. A. Hartigan, C.B., C.M.G., D.S.O., the new Director-General of the Army Medical Services.

A luncheon to celebrate the jubilee of the Society for the Study of Inebriety will be held at the Langham Hotel, London, W., on Tuesday, April 10th, at 1.30 p.m., with the president, Sir Humphry Rolleston, in the chair. Applications for luncheon cards (5s. each) should be sent to the honorary secretary, Dr. T. N. Kelynnack, 19, Park Crescent, W., without delay, accompanied by remittance. The annual meeting of the society will be held at 11, Chandos Street, W., on the same day at 4 p.m., when Sir Humphry Rolleston will deliver a commemorative oration on "The Aims and Work of the Society for the Study of Inebriety during the Fifty Years of its Existence."

Sir Austen Chamberlain and the Standing Committee of the Ross Institute have invited members of the Indian Tea Association and their friends to the London School of Hygiene and Tropical Medicine, on March 19th, at 4 o'clock, when Dr. G. C. Ramsay will demonstrate by a cinema film: "Malaria Control on Tea Estates in Assam and Bengal," and Dr. G. P. Crowden will give a short demonstration on the principles of heat insulation for human comfort in buildings, coolie lines, etc.

On Friday, March 23rd, at 8.45 p.m., at the Princess Elizabeth of York Children's Hospital, Shadwell, E., Dr. S. V. Larkey, professor of medical history in the University of California, will speak on "Superstition and Medicine in Elizabethan England." Dr. Herbert R. Spencer will be in the chair. Visitors are welcomed.

A meeting of the Medico-Legal Society will be held at 11, Chandos Street, W., on Thursday, March 22nd, at 8.30 p.m., when Mr. D. H. Kitchin (barrister-at-law) will read a paper on "Heart Disease in Workmen." The paper will be followed by a discussion.

A meeting of the Royal Microscopical Society will be held, at B.M.A. House, Tavistock Square, W.C., on Wednesday, March 21st, at 5.30 p.m., when papers will be read by Dr. E. S. Horning and Mr. Horace Beck.

The Fellowship of Medicine and Post-Graduate Medical Association announces that the tenth lecture-demonstration, by Dr. Clark-Kennedy, at 11, Chandos Street, will be given on March 20th, at 2.30 p.m. A week-end course in chest diseases will take place at the Brompton Hospital on March 24th and 25th, occupying the whole of each day. Other forthcoming courses include infants diseases, at the Infants Hospital, April 9th to 21st; proctology, at St. Mark's Hospital, April 9th to 14th; rheumatism, at the British Red Cross Clinic, April 10th to 26th (on Tuesday and Thursday evenings); medicine and surgery, week-end course at Southend General Hospital, April 14th and 15th. A series of evening lectures, suitable for M.R.C.P. candidates and for the general practitioner, will be given by Dr. Philip Ellman on "Chronic Diseases of the Chest in General Practice," on Wednesday and Friday evenings during April. Details of these lectures and of the special courses may be obtained on application to the Fellowship (1, Wimpole Street, W.).

A lecture (in English), dealing with his recent investigations on allergy in tuberculosis, by Professor Franz v. Gröer, head of the paediatric department of the Medical Faculty at the University of Lemberg, will be given in the theatre of the Lister Institute, Chelsea Bridge Road, S.W., on Monday, March 19th, at 5 p.m. All interested are cordially invited.

At a meeting of the Eugenics Society in the Linnean Society's Rooms, Burlington House, Piccadilly, on Tuesday, March 20th, at 5.15 p.m., Professor R. J. A. Berry, M.D., will give a lantern demonstration on some modern views of the human mind and its disorders. Sir Humphry Rolleston will take the chair.

The first Clarke Hall Lecture, on "The Ethics of Penal Action," will be delivered in the hall of Gray's Inn, W.C., on Monday, March 19th, by the Archbishop of York. The Lord Chancellor will take the chair at 5.30 p.m.

A medical congress will be held at Tunis under the presidency of Dr. Charles Nicolle, professor at the Collège de France, from March 21st to the 24th.

Country Life for March 10th contains a well-written and admirably illustrated article on Gonville and Caius College, Cambridge, of which foundation a good many of our readers are members.

Messrs. H. K. Lewis and Co. Ltd. announce for immediate publication the new edition of the late R. Prosser White's *Dermatoglyphs, or Occupational Affections of the Skin*. The author had completed the final revision of the proofs before his fatal seizure. The volume will include, as a memoir of the author, the obituary notice by Dr. W. E. Cooke which appeared in this *Journal*, together with a portrait and a reproduction of Dr. Prosser White's characteristic bookplate.

Punch celebrated the centenary of George du Maurier in a special supplement to last week's issue. The publishers make the claim on behalf of du Maurier that he was "an early apostle of eugenics who, long before the cult of athletics had begun to affect the stature and build of English girls, devoted his pencil to glorify the Junoesque type of English beauty." The pictures are prefaced by an appreciation of du Maurier from the pen of Mr. Guthrie ("F. Anstey"), the author of *Vice Versa* and *Voces Populi*, and brother of the late Dr. Leonard Guthrie, who wrote much for these columns. Now comes news of the death, on March 10th, of Anstey Guthrie himself.

Two £100 scholarships—at Port Regis Preparatory School, Broadstairs—established by Sir Milsom Rees for sons of medical practitioners, have been awarded to L. A. Beveridge, son of Dr. Alexander Beveridge of Dinas Powis, Glam., and to J. A. C. Morris, son of Dr. Cameron Morris of Gloucester Terrace, W.2.

Mr. George Alexander Morrison, M.A., LL.D., has been elected to fill the vacancy in the combined Scottish Universities Parliamentary constituency caused by the death of Mr. D. M. Cowan, M.P.

M. Louis Marin, a member of the *Chambre des Députés*, has succeeded M. Emile Lisbonne as the French Minister of Health and Physical Education.

Dr. Hugo Braunn, extraordinary professor at the Frankfurt Institute of Hygiene, has been appointed professor of hygiene at Stamboul.

After nearly fourteen years of service as honorary director of the Institute of Medical Psychology Dr. H. Crichton-Miller, who was also its founder, has been obliged to resign the directorship owing to pressure of other work. He remains on the staff of the Institute as honorary senior physician, and is also a member of the council. Dr. J. R. Rees has been appointed medical director with two assistant medical directors, Dr. Henry V. Dicks and Dr. Mary C. Luff. The Institute announces that, after the very long period that the waiting list has been closed, it has now been found possible to reopen it for patients (from outside the L.C.C. area) who can attend at any hour of the day. The list for evening treatment of adults is still lengthy, and therefore names cannot be entered on it at present.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Aitiology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Midsecre Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumshigh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Callosities

"PERPLEXED" (Surrey) asks for suggestions in the treatment of callosities under both big toes and at the base of the big toes and behind the small toes in a man of 69. He has tried bathing, painting, and ung. ac. salicyl. He has to be on his feet all day at work. The callosity under one big toe is very hard along the nail.

Vomiting after Appendicectomy

"W. T." suggests—quite at random, not knowing details—that "Perplexed's" patient (March 10th, p. 468) may have an oesophageal or a pharyngeal pouch causing the vomiting during meals.

Income Tax

Purchase of Practice—Valuation of Book Debts

"DIGNITAS" bought a practice as from December 31st, 1932, at a round figure to include outstanding book debts, which amounted to about £500 gross. His predecessor estimates the value of those debts at £100, and claims to close his final account for income tax purposes with that sum. How is "Dignitas" affected?

* In the first place "Dignitas" may elect to have his own liability dealt with as if he were starting a new practice as from January 1st, 1933. In that case he would ignore his predecessor's debts and any receipts from them entirely. This is simple enough in theory, but rather difficult to apply in practice. The other alternative is to bring in the book debts at January 1st, 1933, at their value—£100, if his predecessor's estimate is correct—and at the end of the year bring in the corresponding value—for example, if the gross debts are then £600, "Dignitas" could fairly contend that, as £500 gross was brought in at £100 value, £600 should be brought in as one-fifth of £600—that is, £120.

Payments to Children under Deed

"Q" has an income of £800 per annum, and pays each of his two children (both adults and unmarried) annuities of £100 each. The children have no other income, and the annuities are secured, by a legal document, for at least seven years. Can a rebate be claimed? "Q" also wishes to know the title and publishers of a practical book on income tax for professional men.

* The question of annuities payable to children or others is dealt with in Section 20 of the Finance Act of 1922. It is a complicated provision, but it seems clear that in the circumstances the annuities paid by "Q" are "income" of the children for tax purposes, provided that "Q" has no power of revocation of the grant which he can exercise without the consent of any other person. (The necessity for his wife's consent is not sufficient for this purpose.) As the income of the children it is they, and not "Q," who have any right of claiming rebate;

and that right is limited to what tax they have suffered. "Q" should therefore deduct tax when paying the annuities, and the children can claim repayment of the tax so deducted. If tax has not so far been deducted, an adjustment should be made when the next payment falls due, or earlier if possible. A useful little book is *Income Tax and the Professional Man*, published at 4s. 6d. by Crosby, Lockwood and Son, Stationers' Hall Court, Ludgate Hill, E.C.4.

LETTERS, NOTES, ETC.

Use of Quinine in Normal Labour

Dr. L. B. SHINKIN (Highbury Hill, N.5) writes: Dr. A. G. Hawthorne English's letter (January 6th, p. 25) prompts me to relate my personal experience. On reading Dr. Douglas Mitchell's letter (July 15th, 1933, p. 126) I decided to try his method, and for this purpose I selected two young normal primigravidae, whose pregnancies were normal in every respect. They were given tablets of quini. sulph., 5 grains, i.d.s., p.c., for their last four to five months of pregnancy. The results and advantages of this treatment, however, were not obvious. In both cases the duration of labour was not shortened and no improved uterine functions were noted. In fact, the duration of labour was rather prolonged and the uterine contractions were weak and infrequent, resembling a slight degree of uterine inertia, which had to be counteracted by pituitrin injections. In one of these two cases so tedious and slow were the uterine contractions, even after pituitrin injections, that forceps had to be applied (after twenty-four hours in labour). In each case the puerperium was normal.

All in the Day's Work

Details have now reached this country, through the columns of the *Shanghai Times*, of the kidnapping and escape from death of Dr. R. Cecil Robertson, head of the division of pathology and bacteriology of the Henry Lester Institute of Medical Research, Shanghai, and a member of the British Medical Association. On January 31st Dr. Robertson left his home in his car for the institute with his chauffeur and the 8-year-old son of his Chinese cook, who was to be vaccinated that day. A wheelbarrow, pushed suddenly in front of his car, brought it to a standstill, whereupon four Chinese in black gowns jumped into it, ejected the chauffeur, and drove off swiftly towards Chinese territory. Dr. Robertson put up a fierce fight, during which he was twice shot at; appeals for help to Chinese police and bystanders were ignored. Dr. Robertson explained who he was, and his captors appeared surprised and disappointed, but the car continued its course. Resuming the struggle, one of the Chinese was wounded in the hand by his own revolver, the speed of the car slackened, and Dr. Robertson forced open the car door and jumped out, holding the boy. His captors made no further attack upon him, but drove off rapidly and escaped. Dr. Robertson, who is president of the Shanghai Medical Society, owed his life to the failure of a revolver to fire when in contact with his head. He ascribes the incident to an error on the part of the gangsters, who had presumably proposed to carry off a wealthy Chinese, but mistook the car. He was twice wounded in the war in France, and was awarded the M.C. He went out to Shanghai in 1925, and was at first pathologist to the Shanghai Municipal Council, joining the Henry Lester Institute in 1929.

History of Nitrous Oxide Anaesthesia

With reference to Mr. H. E. G. Boyle's paper "Nitrous Oxide: History and Development," published in the *Journal* of January 27th (p. 153), Mr. Eric Oseroff, managing director of Condensed Gas Co., Ltd., Manchester, has sent us an agreement dated April 27th, 1883, which was entered into between the founder of his firm, Mr. J. E. Blennerhasset, and a Manchester dentist, Mr. J. H. Parkinson, for the sale and delivery of N₂O gas, and appliances for delivering and administering it, within the London area. "As a matter of historical interest it is in a way complementary to some of the dates given in the above-mentioned paper, showing that a definite trade in this gas had been established by another firm as far back as the eighteen-eighties."

Aetiology of Cancer

Dr. A. T. BRAND (Driffield, E. Yorks) writes: In your issue of March 10th a report is given of an address delivered at Bradford-on-Avon by Mr. Comyns Berkeley, a member of the British Empire Cancer Campaign, in which he made the statement that "despite the work of large numbers of research workers in all parts of the world the cause of cancer still remained unknown." In this con-

nexion it is interesting to read the report of the United States Treasury Department of Public Health, Washington, of March 31st, 1933, of the production of a malignant growth in an experimental animal by T. J. Glover, M.D. "The purpose of this report is to place on record the production of metastatic malignancy in one of a group of guinea-pigs inoculated with a culture containing a spore-bearing micro-organism which was isolated, on special medium, from the tissue of a microscopically proved carcinoma of the human breast. The micro-organism was again recovered from the malignant tissue of the animal herein reported. A detailed report will be made at a later date giving the findings on the remainder of this group of guinea-pigs, as well as on a series of other experimental animals inoculated with the same micro-organism. The inoculation of the culture was made in the mammary region of an adult female guinea-pig on November 5th, 1932. The animal was observed at frequent intervals until sacrificed on February 28th, 1933." The report then gives the findings on post-mortem examination, and makes the following comment: "The new growth has apparently risen in breast tissue, resembles lactating mammary acini in histological structure, and is identical in structure in the primary and in the various metastatic masses. In the invasion and destruction of tissue and in the production of distant metastasis it fulfils two of the criteria of malignancy. *Diagnosis*: malignant adenoma with metastases in lymph nodes, omentum, and kidneys." The microscopical findings were made by Surgeon R. D. Lillie of the United States Public Health Service, in charge of the work in pathology, at the National Institute of Health, Washington.

Maternal Mortality and the Newspapers

Dr. J. HORR POOL (Newcastle-on-Tyne) writes: In your issue of March 10th Dr. Lachlan Grant paves the way for a fuller inquiry into the acceptance of medical articles by the "lay press." It is well known that the public are only too eager to read such contributions, and the general practitioner is constantly encountering instances of such "expert advice" in the homes of his patients. As an endorsement of Dr. Lachlan Grant's opinion on the matter I am taking the liberty of quoting from my thesis (1932): "At a time when the lay press is flooded with articles and criticisms of the maternal mortality, the medical profession, already burdened by years of investigations and unable to defend themselves publicly, are using their best endeavours to mitigate the tendencies to such complications. The maternal mortality may be alarming to the layman, but to members of the medical profession it is a grave question, and according to Professor Herbert Spencer, 'eclampsia is one of the bugbears of the profession at the present time.'"

Helping the Doctor

Several readers have told us how touched they are by the kindly thought of a London bookmaker, who writes to them: "Something more than the receiving of bets is required of the bookmaker to-day. Owing to the delay and irregularity with which fees are paid to the members of your profession, and assuming that you are interested in racing, I am prepared to open your account with a weekly credit limit of £5 (five pounds), and allow settlement to be made monthly."

Legal Logic

"X. P. S." writes from Nottinghamshire: "Is the accused drunk?"—"This bugbear of the medical profession has, at long last, been laid by the judicial bench, and gratitude should be expressed by all police surgeons and general practitioners. How simple and expeditious it will be! Q.—"Do you consent to be medically examined?" A.—"Yes." Ergo, not drunk.

Short-wave Diathermy

Messrs. WATSON AND SONS, LTD., 43-47, Parker Street, Kingsway, W.C.2, have issued a ten-page illustrated pamphlet on short-wave diathermy equipment. Reference is made to an apparatus already installed at St. Thomas's Hospital. An account is added of the field of application of this so-called "fever diathermy," which, in addition to mere pyrogenic use, can be employed as an adjunct to normal diathermy in various medical conditions. Two special apparatus are described.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 48, 49, 50, 51, 54, and 55 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 52 and 53. A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 108.

THE PATHOGENIC AGENT IN NORMAL HUMAN BONE MARROW

ITS NATURE AND RELATIONSHIP TO THE LYMPHADENOMA AGENT OF GORDON

BY

ULRICH FRIEDEMANN

(From the Farm Laboratories of the Medical Research Council, Mill Hill, N.W.)

In a previous paper¹ it was shown that when normal human bone marrow is injected intrathecally in rabbits these animals develop a progressive and fatal disturbance of the nervous system, paralysis of the hind legs being a characteristic feature of the late stages. It was recognized that the clinical appearances presented by these rabbits resembled those which M. H. Gordon² had already found in rabbits injected intracerebrally with material derived from human cases of lymphadenoma, but the relationship of the two pathogenic agents was not more closely determined. The nature of the agent contained in normal human bone marrow—whether it is a living or a non-living thing—was also left in doubt. The primary purpose of the present paper is to describe experiments directed towards the solution of these two problems.

Right at the outset I must acknowledge deep indebtedness to Dr. Gordon. To his efforts and kindness I owe all the samples of human bone marrow and viscera used in the series of experiments to be described. I have called these human tissues normal in the present paper. This is because I am satisfied they have represented the conditions present in normal human beings. Actually the specimens have been obtained post mortem from a large variety of pathological conditions and from cases of accidental death.

NATURE AND DISTRIBUTION OF THE PATHOGENIC AGENT

The living nature of the pathogenic agent present in normal human bone marrow would be satisfactorily established if this agent could be passed from rabbit to rabbit indefinitely. Renewed attempts to demonstrate such a passage have failed. Intracerebral inoculation of brain tissue taken from a paralysed rabbit was on one occasion followed by somewhat suggestive symptoms. This is the nearest approach to a positive result that I have seen in the new series of experiments. In the previous paper it was reported that in one experiment there had been evidence of transmission through three generations in rabbits, but we have not seen the like again. Perhaps it is significant that in this apparently successful experiment the first rabbit of the series was injected with bone marrow from a case of pernicious anaemia, but we cannot exclude the possibility that some adventitious virus may have been present. As the facts stand it has to be realized that serial transmission of the bone-marrow agent has not been proved, and that in this direction attempts to show the viral nature of the agent have broken down. Such failure is, however, not very strong evidence for the non-living nature of the agent.

It was thought that some knowledge of the species and organ distribution of the agent might be useful. In numerous experiments intrathecal and intracerebral injection of rabbits has shown that the pathogenic agent under investigation is not present in normal bone marrow of rabbits, guinea-pigs, cats, and horses. The bone marrow of dogs has not been tested: for technical reasons I found it difficult to obtain suitable material. The spleen and leucocytes of normal dogs, however, have been tested a number of times, and have given consistently negative results. Normal human liver and kidney also gave negative results, but normal human spleen produced symptoms similar to those produced by normal human bone marrow, though not with the same regularity. Difficulties arising

from the fact that available samples of human viscera were seldom free from contaminating micro-organisms disappeared when the material to be used in the experiments was heated for one hour at 65° C.

The consistency with which bone marrow from so many species has given negative results, and the fact that human liver and kidney are also innocuous, disposes finally of the possibility, discussed in the previous paper, that human bone marrow acts simply by stirring up some virus normally present in the rabbit's brain. The histological changes which follow the intrathecal and intracerebral injection of normal human bone marrow and spleen have not been investigated. For want of some better term we spoke of the condition as an encephalitis in the previous paper, and may do so again in this, but I do not wish to be misunderstood: the term is not used to indicate an opinion as to the ultimate nature of the process.

JOCHMANN'S PROTEOLYTIC FERMENT AND THE UNKNOWN AGENT

The peculiar species and organ distribution of the pathogenic agent under investigation closely resembles the distribution of a proteolytic ferment studied by Jochmann.^{3,4,5} This ferment, Jochmann showed, is present in the bone marrow, spleen, and leucocytes—but not elsewhere—of man, monkeys, and, to a slight degree, dogs. It could not be found in any other species of animal examined. Jochmann considered that the ferment is peculiar to the leucocytes of certain species, and that in these species the occurrence of the ferment in spleen and bone marrow is due solely to the presence of leucocytes in these organs. I have undertaken experiments to determine whether the agent which is present in human bone marrow and spleen, and which is pathogenic for rabbits, has properties similar to those of the ferment described by Jochmann.

Jochmann found that his ferment is rapidly destroyed at 70° C., withstands 65° C. for one hour without appreciable diminution in activity, and persists indefinitely at temperatures of 55° C. and under. He, along with Lockemann,⁶ described a method by which the ferment can be extracted. They used bone marrow and spleen principally. Tissue is incubated for twenty-four to forty-eight hours at 55° C., during which time a considerable amount of autolysis takes place. Then five volumes of alcohol-ether (two volumes of absolute alcohol to one of ether) are added. After twenty-four hours at room temperature the supernatant fluid is removed and discarded; then the deposit is dried in a desiccator and afterwards mixed with an equal volume of 50 per cent. glycerin in water. After another twenty-four hours at room temperature the still undissolved deposit is removed and discarded, and the supernatant glycerin is mixed with five times its volume of alcohol-ether (proportion of alcohol and ether as before). This mixture is allowed to stand for twenty-four hours at room temperature to give time for the precipitation of material which has gone into solution in the glycerin. This final precipitate contains the ferment. The ferment is soluble in saline, and was generally used by Jochmann made up to twice the volume of the original tissue.

The question now was whether the agent which is present in human bone marrow and spleen, and which is pathogenic for rabbits, will withstand the severe treatment to which Jochmann submitted his leucocytic ferment. To obtain material for the necessary experiments human

bone marrow and spleen were extracted by the Jochmann-Lockemann method. In both cases the final saline solution was somewhat turbid at the time it was made. In the cold room a precipitate formed. This was spun down and removed. The clear brownish supernatant fluid was taken for use in the various tests to be described. Both the extract of bone marrow and the extract of spleen were shown to contain the leucocytic ferment, which, as already mentioned, is a proteolytic ferment. In the presence of either extract litmus milk gradually became clear owing to the action of the ferment on the casein.

Intracerebral and intrathecal injection of these first extracts which I had prepared by Jochmann and Lockemann's method produced symptoms resembling in all respects those which follow similar injections of saline suspensions of fresh tissue of human bone marrow and spleen. In most of the rabbits employed in these tests there was an incubation period of four days, during which the animals remained in apparently perfect health: in only one case was the incubation period as short as twenty-four hours.

A. lytic action on brain constituents seemed possible, and several *in vitro* tests were made, all with the same result. Only one will be described.

The brain of an adult 2,000-gram rabbit was ground in 10 c.cm. saline in order to obtain a very thick suspension. Two similar tubes were taken: into one was placed 4.5 c.cm. brain suspension and 0.5 c.cm. saline, and into the other 4.5 c.cm. brain suspension and 0.5 c.cm. of Jochmann extract of human bone marrow. Both tubes were incubated at 55° C. After twenty-four hours the mixture in the tube containing emulsion and saline was found to be coagulated; it would no longer flow when the tube was inverted. In contrast to this the mixture of brain suspension and Jochmann-Lockemann extract had become more fluid in the twenty-four hours, and this process of liquefaction progressed steadily during the remaining days of the experiment. When comparative tests were made the extract of bone marrow proved to be a rather more powerful lytic agent than the extract of spleen. It is unlikely that the lysis of brain tissue just described can have been due to the presence of a lecithinase in the extracts. I made a number of experiments, but was unable to find such a ferment. An ovo-lecithin was used in the tests, and the proportions of extract and substrate were varied over a considerable range. Red blood corpuscles of the sheep were used as a test for split products due to the action of lecithinase.

Various modifications of Jochmann and Lockemann's method of extraction have been tried. The pathogenic agent, as also the proteolytic ferment—if that is a different thing—was found to be insoluble both in acetone and in methyl alcohol. Sometimes tissue for extraction has been treated with one and then the other of these two reagents between the period of autolysis and the first treatment with alcohol-ether. There is no obvious advantage in this, and, in fact, too prolonged an exposure to either methyl alcohol or acetone may, I suspect, result in a final product of somewhat reduced potency.

These modifications of Jochmann and Lockemann's method are mentioned chiefly as a further indication of the stability of the agent under investigation. It was found, too, that autolysis of the tissue is not necessary; this means that Jochmann and Lockemann's preliminary incubation can be omitted. Perhaps the simplest method of extraction which I have used is the following. The tissue—bone marrow or spleen—is extracted with acetone. At the end of fifteen minutes the undissolved material is collected on filter paper in a Buchner funnel, and washed first with absolute alcohol and then with ether. The resulting dry powder is then mixed with an equal volume of 25 or 50 per cent. glycerin in saline. At the end of twenty-four hours the undissolved material is spun out and the supernatant glycerin is mixed with five times its volume of alcohol-ether (two volumes of absolute alcohol to one volume of ether). The precipitate is removed and then taken up in saline.

To test whether the pathogenic agent is present in human leucocytes the following experiment was carried

out. Some 250 c.cm. of my own blood was run into a flask containing citrate solution. The blood cells were washed several times with citrate in the ordinary way, and then with saline. Finally, the leucocyte layer was removed and suspended in a very small volume of saline. Many red cells were still present, but this dilution was of secondary importance, since the cellular suspension obviously contained a greater concentration of leucocytes than had been present in the suspension of bone marrow employed for the intrathecal and intracerebral injections. Two rabbits, each of about 2,000 grams in weight, received intrathecally 0.4 c.cm. of the leucocyte suspension. Characteristic and fatal encephalitic symptoms developed in one animal, and showed that the pathogenic agent is present in human leucocytes just as the leucocytic ferment of Jochmann is.

If it could be shown that the pathogenicity of Jochmann-Lockemann extracts of human bone marrow, spleen, and leucocytes runs parallel with the ferment activity, then the identity of the pathogenic agent might be considered as established. This method of investigation has not been attempted. My experience is that quantitatively accurate comparisons are very difficult to obtain by the method of intrathecal and intracerebral injection in rabbits.

DISCUSSION

The conclusions drawn from the experiments which have been described above may now be briefly stated. First, the conclusion is drawn that the agent which is present in human bone marrow, spleen, and leucocytes, and which is pathogenic to rabbits, cannot be a virus. I find it impossible to believe that a living thing could survive the drastic treatment demanded by the Jochmann-Lockemann method of extraction. Secondly come conclusions as to the relationship between the pathogenic agent and the ferment. Here somewhat greater caution is necessary, but it has to be admitted that identity is suggested very strongly by the similarity in species and organ distribution of the two, by the similarity in resistance to heat, and by similar stability in the presence of alcohol, ether, alcohol-ether, methyl alcohol, and acetone.

But although I am satisfied that the pathogenic agent found in human spleen, bone marrow, and leucocytes cannot be a living virus, the whole phenomenon still remains a puzzle. The effects of intrathecal and intracerebral injections in rabbits differ from the known effects of chemical substances—except those of toxins like diphtheria and tetanus—in that they are progressive in character. In this progressive character, following an incubation period, there is a close resemblance to infectious diseases. Thus in a prolonged case the clinical course may run much as follows. After an incubation period of about four days a progressive rigidity of the hind legs sets in. A week or so later these symptoms subside, and the animal gradually returns to a more or less normal condition, which may persist for a week or two. Then the hind legs become paralysed, and a week or two later the fore legs also become paralysed. Eventually the animal dies of a general paralysis.

Lack of material has prevented me from testing whether the agent which Gordon discovered in lymphadenoma glands can be extracted by Jochmann and Lockemann's method, but a prolonged experience with the pathogenic agent in bone marrow permits a closer comparison of the clinical manifestations of the two than was possible at the time of publication of the paper by Friedemann and Elkeles in 1933. It is now clear, for instance, that provided the route of administration is the same there is no demonstrable difference between the clinical effects produced by the agent from bone marrow and those produced by the agent from lymphadenoma glands. Gordon

described a rigidity of the legs as characteristic of his rabbits. He used intracerebral injections. Exactly the same thing is observed in rabbits which receive bone marrow intracerebrally. When, however, bone marrow suspension is given intrathetically, as in our original experiments, flaccid paralysis is the characteristic feature, though occasionally rigidity is seen. When bone marrow is injected intracerebrally, then rigidity is the characteristic consequence, just as in Gordon's rabbits. It is all a matter of technique. We have found, too, that, when tissue emulsions have been heated for one hour at 65° C. and then injected, it matters little whether the intracerebral or the intrathetical route is used; rigidity of the legs is a common feature in either case. Further, Gordon reported that his agent is remarkably stable in the cold. I find that the stability of the bone-marrow agent varies with the conditions of the experiment.

If bone marrow be ground in saline and then left in the cold room (4° C.) it loses its pathogenic activity rapidly—often within an hour. Whether there is an actual destruction of the pathogenic agent under these conditions has not been determined. The observed facts are that, when bone marrow is rubbed up in saline as described, a coagulation of the fatty matter soon sets in, clumps are formed, and the presence of the agent can no longer be demonstrated. Probably the agent is gathered up in the clumps. With alteration in technique the results alter. In the presence of 5 per cent. glycerin in saline the clumping sets in very slowly and the clumps are soft and easily broken down again. If the soft coagulated material be rubbed up in a mortar the fatty matter may be removed without difficulty. Glycerinated material has now been kept for six days in the cold room, rubbed up in a mortar, spun free of cells and gross particulate matter, and has then proved pathogenic for rabbits. Both agents are alike, too, in that they withstand a temperature of 65° C. Thus we reach the conclusion that the agent found in normal human bone marrow resembles the agent found in lymphadenoma glands in every material particular. Identity cannot, however, be said to be completely and finally established as yet.

CONCLUSIONS

Studies of the agent which is present in normal human bone marrow, and which Friedemann and Elkeles found to be pathogenic for rabbits, have been continued.

It is shown that this agent cannot be a living virus, since it withstands treatment which no living virus could be expected to withstand.

It has now been demonstrated that the agent, in addition to being present in human bone marrow and spleen, is present in human leucocytes.

The peculiar species and organ distribution which is displayed by this agent has been shown to be paralleled by the distribution of the proteolytic ferment which Jochmann found in normal human leucocytes. Whether the agent and the ferment are really identical remains to be finally established.

Increased familiarity with the pathogenic agent which we have studied still reveals no material difference between it and the agent which Gordon discovered in glands taken from cases of human lymphadenoma.

My indebtedness to Dr. Gordon has been mentioned already. It is now my pleasure to acknowledge financial assistance from the Rockefeller Foundation and the hospitality extended to me by the Medical Research Council at their Mill Hill laboratories.

SOME PROPERTIES OF THE ENCEPHALITOGENIC AGENT IN LYMPHADENOMATOUS TISSUE

WITH FURTHER OBSERVATIONS ON GORDON'S BIOLOGICAL TEST IN THE DIAGNOSIS OF HODGKIN'S DISEASE*

BY

C. E. VAN ROOYEN, M.B., CH.B.

ASSISTANT, BACTERIOLOGY DEPARTMENT, EDINBURGH UNIVERSITY

Much interest has been aroused in the aetiology of Hodgkin's disease by the work of Gordon (1933), who found that rabbits injected intracerebrally with lymphadenomatous tissue frequently developed highly characteristic nervous lesions. This reaction applied as a biological test has proved valuable in the differentiation of Hodgkin's disease from other forms of lymphatic hyperplasia (van Rooyen, 1933), but the exact nature of the pathogenic agent and its aetiological relationship to the disease is still obscure. An attempt has therefore been made to gain further information concerning its nature by a study of its behaviour towards certain physical and chemical agents, and the data obtained, together with further observations on the clinical value of the biological test, are incorporated in this paper.

Recently Friedemann and Elkeles (1933) have reported that the intracerebral inoculation of rabbits with bone marrow derived from cases of acute leukaemia and pernicious anaemia produces effects very similar to those described by Gordon. In May, 1933, the writer made a similar observation with bone marrow removed from a case of acute myelogenous leukaemia, and there was certainly a close resemblance between the experimental condition produced by this material and the syndrome resulting from the inoculation of lymphadenomatous tissue. The further question therefore arises as to whether any relationship exists between the pathogenic agent present in the bone marrow in the leucoses and that present in the lymphatic glands in Hodgkin's disease.

FURTHER RESULTS WITH THE BIOLOGICAL TEST

The following are a list of cases in various parts of the country which have been investigated by means of the biological test.

Biological Diagnostic Test (Gordon)

ANALYSIS AND DISCUSSION OF RESULTS

Gordon's test has, as tabulated above, been applied to clinical and post-mortem material derived from twenty separate cases of Hodgkin's disease, and fifteen of these were found to give a positive result. Other cases of lymphadenohypertrophy due to a variety of different pathological conditions have likewise been submitted to the test, but found to be negative. The test is exceedingly helpful as an aid to the diagnosis of Hodgkin's disease when the histological appearances are not entirely typical of the condition.

Effect following Variations in the pH of Tissue Suspensions

For example, in Case H40 death appeared to be due to bronchial carcinoma with secondary metastasis in the lymphatic glands and elsewhere. Microscopical findings, however, led to considerable diversity of opinion with regard to the diagnosis, and there was much speculation as to the nature of the condition. The case, however, gave a strongly positive reaction in the rabbit, and was ultimately proved to be one of Hodgkin's disease; for this patient had already, some years previously, been under the care of an institution elsewhere, at which biopsy had been performed and the histological section found to be typical of Hodgkin's disease. This is the second case I have encountered in which the test has proved to be of great value; the first of them has been recorded (Ogilvie and van Rooyen, 1933), and it is hoped that these findings may prove of interest to other workers.

It will be observed from the table that certain specimens of glands produced more severe lesions in the rabbit than others.

For example, Cases H33, H40, H15, and H18 all yielded a strong reaction in animals injected with emulsified glands soon after their excision from the patient. The remainder, however, had to be emulsified in broth (pH 7.1) and stored at -4° C. for seven days (at least) before a satisfactory result could be obtained in the animal. A few were entirely negative, and preliminary treatment did not influence the results.

In view of this marked variability in pathogenicity exhibited by different specimens, an attempt was made to ascertain whether the reaction was dependent on the predominance of any particular type of cell present in the lymphatic gland. Sections were therefore made from glands which gave strong, weak, and negative reactions respectively in the rabbit, and these were examined microscopically in order to detect any demonstrable differences in histopathological appearance. No significant differences, however, could be found, and attempts to correlate the syndrome with the presence of any particular type of cell seen in the histological picture described by Sternberg and Reed were unsuccessful. The syndrome does not depend on the presence of lymphocytes or immature forms of haemopoietic cells, for enlarged glands removed from cases of lymphosarcoma and leukaemia give negative results. It is not related to Sternberg-Reed giant cells, for glands containing large numbers of them appeared to be no more pathogenic to the rabbit than those which contain only a few.

This point is well illustrated in two cases of Hodgkin's disease, H19 and H40 respectively. The former of these revealed histologically numerous giant cells, but, nevertheless, repeatedly yielded a negative result (glands being excised both at biopsy and at necropsy). The latter, on the contrary, exhibited only a few of them but gave a strongly positive result.

The presence of eosinophilia does not appear to be of any consequence either, for the syndrome has been reproduced with tissue revealing only occasional eosinophil cells in histological sections. The result noted with bone marrow may help to throw some light on the problem, but the subject requires further study.

OBSERVATIONS ON THE BONE MARROW IN A CASE OF ACUTE MYELOGENOUS LEUKAEMIA

During the course of this work different tissues derived from various pathological conditions have been introduced into the brains of rabbits, including bone marrow derived from two cases of Hodgkin's disease. Only one result of any significance was obtained, and this is recorded below. It concerns the bone marrow removed from the femur in a fatal case of acute myelogenous leukaemia. The specimen was one which exhibited chloromatous change and contained little or no visible fat. The follow-

ing clinical and post-mortem notes describe the subject from which the specimen was procured:

C. F., female, aged 35, was under the care of Professor Bramwell at the Royal Infirmary, Edinburgh. She complained of progressive anaemia for several weeks, bleeding, ulceration, and swelling of gums. Metrorrhagia and menorrhagia had occurred during last ten days. There was ecchymosis on trunk and legs. Red blood cells 1,900,000 per c.mm., haemoglobin 33 per cent., colour index 0.8; white blood cells 7,000 per c.mm.—reticulocytes 1 per cent., polymorphs few, small lymphocytes increased, myelocytes and megakaryoblasts numerous. Post-mortem examination revealed leucoblastic reaction and deposit of chloromatus pigment in the marrow. Cloudy swelling of myocardium, liver, and kidneys was observed. Petechial haemorrhages into the epicardium and gastric mucosa were seen. The spleen was slightly enlarged, and gave a positive prussian-blue reaction. Of eight rabbits injected intracerebrally with this tissue after three to four days all developed a spastic condition of their hind limbs, which closely resembled the encephalitic syndrome of Gordon. On the other hand, a lymphatic gland removed from the same patient gave a negative result in the biological test.

Whether the encephalitogenic agent in bone marrow described by Friedemann and Elkeles (1933), and also by the writer of this paper, is identical with that present in lymphadenomatous tissue, can only be decided after further investigation. It is hoped that information supplied in this paper concerning some physical properties of the latter might offer help towards a solution of the problem.

PROPERTIES OF THE ENCEPHALITOGENIC AGENT IN GLANDS AFFECTED WITH HODGKIN'S DISEASE

Optimum Conditions Necessary for Activation of Pathogenic Agent from Tissue: Influence of pH

Some earlier results showed that the pH of broth used for the emulsification of tissue appeared to influence the pathogenicity of suspensions in the rabbit's brain. Accordingly, in these experiments an endeavour was made to discover the optimum hydrogen-ion concentration necessary for the activation of the pathogenic agent from lymphadenomatous tissue. It has previously been noted by van Rooyen (1933) that material procured from different cases of this disease showed marked variation in their pathogenicity to the rabbit. Hence it was necessary to estimate the degree of activity of each specimen of gland by the preliminary inoculation of rabbits with varying dilutions of tissue suspensions. An approximate estimation of the minimum pathogenic dose to the rabbit could thus be arrived at for each specimen employed. The proportion of tissue present in the emulsions varied from 1 in 20 to 1 in 40 parts per c.cm., of which the dose administered was 0.4 c.cm. intravenously and 0.4 c.cm. intracerebrally. Desiccated material derived from different cases of Hodgkin's disease was weighed, emulsified, and diluted in broth varying in range from pH 5 to pH 10, and then used for intracerebral inoculation (*vide supra*). Animals were injected both immediately after each suspension was prepared and after it had stood for periods varying from three to twenty-three days in a refrigerator at -40°C . The latter procedure was adopted in order to elicit further information concerning the nature of changes which occurred in these tissue suspensions when maintained at low temperatures, for varying periods of time, as in Gordon's original technique.

TECHNIQUE OF pH ESTIMATION

The method adopted was to obtain varying degrees of pH by adding N/20 NaOH to 5 c.cm. of buffered phosphate broth; 0.5 c.cm. of a 0.01 per cent. aqueous solution of phenol-red was used as indicator, and, by comparison with a standard set of indicator tubes readings were made over the range pH 6.6 to pH 8. Above and below these figures a universal

indicator and bromthymol-blue were used as indicators. The above method could not be used when working with smaller quantities of fluid, and the pH of these had to be ascertained by means of a B.D.H. capillator outfit, phenol-red, brom-cresol-purple, and thymol-blue being used as indicators in order to obtain the desired pH range.

The above results strongly indicate that the agent present in Hodgkin lymphatic tissue only exhibits maximum activity within a comparatively narrow range of pH (6.8 to 7.3). For example, whilst a 1 in 40 suspension of gland tissue emulsified in broth of pH 7 was found to be active both immediately and after three days, tissue suspended in broth of pH 5.6 or pH 8 produced no effect in the rabbit when tested under identical conditions.

The same common characteristic has been demonstrated in tissues derived from three different cases of Hodgkin's disease. Efforts made to reactivate tissues which had been previously rendered inactive by suspension in broth of pH 5 or pH 8 (*vide supra*), by the addition of fresh alkali or acid, were without success. It was therefore concluded that this inactivation was an irreversible reaction.

Reduction in Pathogenicity of Tissue Emulsions to the Rabbit by the action of Sodium Hydroxide, Sodium Bicarbonate, Ammonia, and Ammonium Carbonate

In view of the preceding experiments concerning the influence of pH on this agent, attention was next paid to the effect of treating highly pathogenic suspensions of Hodgkin lymphatic tissue with certain alkalis, prior to the intracerebral inoculation of rabbits.

Allusion has already been made to the difficulties encountered in attempting to arrive at an accurate standard of dosage for the rabbit. Accordingly, it was possible only to compare the relative severity of changes produced in two rabbits, the one inoculated with the usual material and the other with the same tissue after it had been treated with alkalis.

It was thus observed that the treatment of a highly pathogenic suspension of tissue with 1 per cent. NaOH for twenty-four hours at -40°C . resulted in considerable loss of pathogenicity for the rabbit. The effect was even more noticeable with less active tissue which could be inactivated by 0.5 per cent. liquid ammonia or ammonium carbonate within twelve to twenty-four hours. The effect appears to be quantitative in nature, for it depends on the activity of the tissue, the concentration of alkali, and the duration of its action. As previously, attempts to reactivate inactive material by neutralization with acid were unsuccessful.

FILTRATION EXPERIMENTS

Previous experiments to demonstrate the filterability of this pathogenic agent were unsuccessful. Since my findings have suggested that a comparatively narrow range of hydrogen-ion concentration is necessary for the satisfactory demonstration of this pathogenic agent, it is probable that variations in pH resulting from the act of passage through an earthenware candle may have been sufficient to account for the inert filtrates reported by Gordon (1932-3). I have overcome this difficulty by the employment of specially treated filter candles, and have been able to demonstrate the filterability of Gordon's pathogenic agent to the rabbit.

Technique of Filtration

Two types of filters were used, the one a Berkefeld (British), and the other a Seitz (EK) fine-pore asbestos disk $1\frac{1}{2}$ inches in diameter. The candle of the former and the disk of the latter were first treated with buffered phosphate broth of pH 6.7, by allowing the fluid to act on the two elements for twelve

hours at 26° C. They were then put into usc. Material used for filtration was a desiccated lymphatic tissue derived from a typical case of Hodgkin's disease that had previously yielded a strongly positive biological reaction. One gram of tissue was emulsified in 10 c.cm. of sterile broth of pH 7.1, and then placed in a refrigerator at -4° C. for seven days. Thereafter it was centrifugalized at 1,500 revolutions per minute for twelve minutes, and the supernatant fluid withdrawn with a sterile pipette. To this was added 0.5 c.cm. of an emulsion of *B. prodigiosus* prepared in broth of pH 7.1 standardized to approximate the density of Brown's opacity tube No. 1, and 0.5 c.cm. of a similar suspension of *B. melitensis*, which was also added. The mixture was then divided into two equal parts of 5.5 c.cm., and passed through each filter, a negative pressure of 350 mm. of Hg being applied for a total duration of twelve minutes at room temperature (20° C.). Both filtrates were clear in colour, contained neither *B. melitensis* nor *B. prodigiosus*, and 0.4 c.cm. of each was accordingly introduced intracerebrally and intravenously into four rabbits.

The animals recovered from the operation and remained in good health for a period of four days, after which they all developed the typical encephalitic syndrome. The brain of each animal was then removed and subjected to bacteriological examination. As no growth could be obtained from these by aerobic or anaerobic methods of cultivation after three months, it was concluded that the pathogenic agent was definitely filterable and could pass through both a Berkefeld (British) and the finest-pore Seitz filter. This experiment was repeated thrice with material procured from three different cases of Hodgkin's disease. The most active filtrates were obtained from lymphatic tissue that normally gave a strong positive biological test in the rabbit (van Rooyen, 1933), the material being suspended in high concentration in buffered phosphate broth of pH 7.1, and the pH of the filtrate being kept below pH 7.1.

THE ACTION OF ADSORPTIVE AGENTS

In these experiments emulsions of Hodgkin lymphatic tissue were first treated with adsorptive agents, and then injected into rabbits. Some interesting facts have been obtained, but these are of limited value, for only the behaviour of the agent at pH 7.1 could be investigated. This has been unavoidable, because the range of pH over which this agent exhibits activity is small (pH 6.8 to 7.3), and consequently it was not possible to conduct experiments on the effect of adsorbents at different hydrogen-ion concentrations.

Technique

Two and a half cubic centimetres of a 1 in 20 emulsion of Hodgkin lymphatic tissue prepared in broth of pH 7.1 containing 0.25 per cent. phenol was added to each of four different conical flasks containing 0.2 gram of sterile kieselguhr, pulverized vegetable carbon particles, calcium sulphate, and emulsified normal rabbit's brain. Also a fifth flask containing 45,770 millions of dead *B. typhosus*, a sixth with 37,870 millions of dead *B. coli*, and a seventh empty one, which acted as the control. The number of bacteria were calculated as follows: twelve twenty-four-hour agar slope cultures of each organism were heated to 65° C. for thirty minutes, emulsified in 10 c.cm. of 0.86 per cent. physiological saline solution of pH 7.1, standardized to approximate the density of Brown's opacity tube No. 10, and 10 c.cm. of the emulsion centrifugalized to yield the desired number of organisms. All seven flasks were mounted on a slowly oscillating electrical shaking machine, and placed in an incubator at 37° C. for four hours. Thereafter the contents of each flask were transferred with a sterile pipette into separate test tubes, and centrifugalized at 2,100 revolutions per minute for twelve minutes; the supernatant fluid was withdrawn from each tube, divided into two equal parts, and injected into two rabbits in the usual manner.

Of the fourteen animals injected, the two inoculated with control material developed the syndrome and died after five to seven days: likewise also did those injected with material treated with *B. typhosus*, *B. coli*, and calcium sulphate respectively. Slight loss of pathogenicity followed adsorption by normal rabbit brain, for these animals developed a less severe lesion than did the controls. Greater loss was observed after treatment with carbon, as one of the rabbits developed only a slight illness lasting two days and the other escaped completely. After treatment with kieselguhr, however, tissue suspensions of Hodgkin lymphatic tissue appeared to be completely non-pathogenic to the rabbit. The above experiment was repeated three times with clinical material supplied from institutions in Edinburgh, Glasgow, and London, and in each case the same result was obtained. It was therefore concluded that the pathogenic agent contained in these glands could be readily adsorbed in neutral solutions by treating with kieselguhr, less so by treating with carbon particles, and least of all by normal rabbit brain.

EFFECT OF DESICCATION

Gordon (1932) stated that the agent was capable of withstanding desiccation, and might be concentrated and rendered more active in glands by first drying them. This finding has been confirmed by the writer in the case of material from Case H28, which showed increased pathogenicity in the rabbit's brain after it had been desiccated *in vacuo* over P₂O₅ at 0° C. for four to six weeks. In consequence of these results, a number of specimens of lymphatic tissues removed from cases of pseudoleukaemia, lymphosarcoma, and two cases of Hodgkin's disease (H9 and H10, which gave a negative result in the rabbit even after prolonged refrigeration) were desiccated, re-emulsified, and then used for inoculation, but with negative results throughout.

EFFECT OF FREEZING TISSUE EMULSIONS TO 190° C. BELOW ZERO

In order to gain information concerning the action of extreme cold *per se* on this pathogenic agent, material derived from four different cases of Hodgkin's disease was investigated in the following way.

Technique

Tissue suspensions were put up in hard glass test tubes and then placed in a small Dewar vacuum flask. A pure specimen of liquid air was next siphoned off from its container into the flask. After twelve minutes' immersion in the fluid, suspensions were withdrawn and set aside to melt at 17.4° C.

On one occasion a desiccated of Hodgkin lymphatic tissue was frozen to -190° C. for twelve hours, after which it was emulsified in broth of pH 7.1, allowed to stand at -4° C. for seven days, and then used for inoculation.

The material appeared to be unaffected by such a degree of exposure to cold. It still retained its pathogenicity to the rabbit, and reproduced the characteristic syndrome after the usual incubation period of three days.

EFFECT OF X RAYS ON THE PATHOGENIC AGENT

Investigations were conducted towards ascertaining whether these rays produced, *in vitro*, any destructive effect on the agent in question.

Small fragments of desiccated tissue weighing from 230 to 350 mg. were placed in a quartz glass test tube (98 per cent. SiO₂ in composition), and then exposed for thirty-five minutes at a distance of 26 cm. to the rays emitted from a Muller W anticathode, utilizing 5 mA at 80 kV. A variety of different dosages were employed in the tests, and the greatest

them was an exposure of 4,545 r, approximately equivalent to unit skin doses.

As far as could be gathered from the results following subcutaneous inoculation, it did not appear that irradiation produced any diminution in the pathogenicity of the material to the rabbit. It was therefore concluded that the agent in these glands responsible for the encephalitic syndrome in rabbits was capable of withstanding considerable doses of x rays.

INSUSCEPTIBILITY OF RABBITS TO REINOCULATION AFTER RECOVERY FROM SYNDROME

Several animals which had recovered from the syndrome were allowed to regain their normal health and weight and then reinoculated with the same material as was used for their first injection. The period which elapsed between the two operations varied from a fortnight in some cases to three months in others. On no occasion, however, was it possible to demonstrate immunity to the second dose; indeed, so far as could be observed, it appeared that the rabbits were even more susceptible to it than before.

HISTOLOGICAL CHANGES IN BRAINS OF AFFECTED RABBITS

As previously stated, rabbits affected with the encephalitic syndrome only showed a slight leucocytic infiltration at the site of inoculation, and occasionally similar changes in the meninges overlying this area. The specificity of the latter was dubious, as its presence was comparatively infrequent, and was sometimes met with in normal rabbits. In a few animals, however, in addition to the foregoing changes, marked perivascular, round-cell infiltration, and "cuffing" was found to occur around blood vessels. The response appeared to be evanescent in type, for these changes were usually best demonstrable about the seventh to tenth days after injection, and apparently disappeared rapidly, irrespective of the state of the animal. No evidence of *Encephalitozoon cuniculi* infection could be found, and consequently the changes were not regarded as being of a spontaneous character. A search for inclusion bodies was carried out by removing the brains of rabbits which had been paralysed for three to six and twelve days respectively, fixing these in Bouin's solution and staining them by Mann's method, but none were found. A few animals which had recovered from the syndrome were examined after six to eight weeks, but the results were negative.

INTRACEREBRAL INOCULATION OF CATS, DOGS, AND FERRETS

Five kittens and two puppies were injected intracerebrally and intraperitoneally with suitable suspensions of lymphatic tissue, but no results were observed to follow after three months' observation. Fifteen ferrets were injected intracerebrally, intraperitoneally, and intracranially with similar material. Twelve of these animals died within two to four weeks, and some of them showed signs of encephalitis prior to death. The animals, however, had not been quarantined before the test in order to exclude ferret distemper, and no definite statement can be made yet regarding the significance of the results. It was also noted, in some of the ferrets which had been injected intracranially, that a small inflammatory nodule developed at the site of inoculation after five to six days, similar to that described by Twort (1930) in the guinea-pig. This part of the work is still in progress.

NATURE OF THE ENCEPHALITOGENIC AGENT: DISCUSSION

Extended observations on Gordon's test have again proved it to be a reliable laboratory method for the

diagnosis of Hodgkin's disease. The specificity of the reaction with lymphatic tissue obtained from this condition appears to be a well-established fact, but the precise nature of the agent—whether a virus, toxic substance, or enzyme—responsible for the syndrome in rabbits is quite obscure. The effects are not due to trauma (van Rooyen, 1933), but seem to result from some pathogenic entity present in lymphoid tissue affected with Hodgkin's disease, and to be demonstrable experimentally by the intracerebral inoculation of rabbits.

In his earlier work Gordon (1932) found it was necessary to place tissue emulsions in a refrigerator at -4°C . for several days before they showed pathogenicity. Since then many other cases of Hodgkin's disease have been investigated, and several have been encountered, both by Gordon (1933) and by the writer, in which tissue has been found to be active when immediately emulsified. This may be due to the fact that the quantity of the agent present in different pathological specimens varies greatly. Thus, when present in large amount in any one case, the immediate trituration and emulsification of the tissue may liberate a sufficient quantity to produce lesions in the rabbit. This presupposes that the pathogenic principle is intracellular either in origin or distribution. It has, in fact, been observed that feebly pathogenic emulsions of tissue may be rendered more active by allowing rapid cytotoxicity to occur—for example, by maintaining it at 37°C . for two to three days, or by intense freezing in liquid air followed by rapid thawing. The fact that fresh tissues may prove active excludes the possibility that the agent is a product of *in vitro* autolysis. The diffusibility of the agent is indicated by the positive results obtained with centrifugized and cell-free suspensions; and should it be of particulate nature, then the particles must be of ultra-microscopic dimensions. The filterability of this agent has been clearly demonstrated.

The work of Friedemann and Elkeles (1933) on bone marrow may throw some light on the problem, and it is of considerable interest, since Medlar (1931) has regarded Hodgkin's disease as a megakaryoblastoma and a tumour having its origin in bone marrow. This might suggest that the pathogenicity of lymphatic tissue is related to its cellular content, but so far no such correlation has been found to exist; moreover, further work is required to ascertain whether the encephalitogenic agent in bone marrow is identical or not with that demonstrated in Gordon's test.

Another question for consideration is the aetiological relationship of this encephalitogenic agent to the clinical condition, but no evidence is available at present which affords any definite indication that it is causally related to Hodgkin's disease, except for its striking association with the disease. Meanwhile, the demonstration of such an agent in bone marrow (normal and pathological) limits the significance to be attached to the encephalitogenic property of lymphadenomatous tissue.

In conclusion, there remains the problem concerning the exact nature of the pathogenic principle in lymphatic tissue, and some information has been obtained on its characters by a study of its behaviour and susceptibility towards certain physical effects. Thus, it exhibits great resistance towards cold and x rays, displays maximum activity in solution at pH 7.1, can be readily adsorbed by kieselguhr, carbon particles, and normal rabbit brain, and is definitely filterable. It has also been shown by Gordon to be capable of withstanding temperatures up to 70°C . for half an hour.

The significance of these facts cannot readily be assessed, because many of the features alluded to above are those which are common to both viruses and toxins, though the peculiar nervous syndrome produced in the rabbit, by analogy with other virus diseases of the central nervous

system, might seem to favour the virus hypothesis. On the other hand, the failure so far to transmit the experimental disease in animals, and the absence of immunity after recovery do not support the view that the active principle is of virus nature. Finally, there is the possibility that the substance may be of the nature of an enzyme, producing specific damage to the central nervous system.

The problem is one of the greatest interest and practical importance, and the data given in this paper are put forward as a further contribution towards its study. Whether or not the encephalitogenic agent is directly related to Hodgkin's disease, the fact remains that it is of clinical importance in the diagnosis of the condition, and as a new pathogenic principle merits the most careful investigation.

CONCLUSIONS

1. Twenty cases of Hodgkin's disease and thirteen other conditions of lymphadeno-hypertrophy have been investigated. Gordon's biological test gave positive results in fifteen (75 per cent.) cases of Hodgkin's disease, and was found to be negative in the others.

2. The occurrence of a reaction in the rabbit closely simulating Gordon's encephalitic syndrome has been observed to follow intracerebral inoculation with bone marrow derived from a case of acute myelogenous leukaemia.

3. The encephalitogenic agent in Hodgkin's disease has been found to exhibit the following properties: (a) The maximum quantity is liberated from Hodgkin lymphatic tissue when buffered phosphate broth of pH 7.1 is used for its emulsification. (b) Alkalis, such as sodium hydroxide, sodium bicarbonate, ammonia, and ammonium carbonate, may all cause considerable reduction in the pathogenicity of active material. (c) Tissue emulsions have been frozen to -190°C . for ten minutes and tissue desiccates for twelve hours, without inactivation. (d) The agent resists exposure to ten unit skin doses of x rays. (e) It can be readily adsorbed in neutral solutions by kieselguhr, less so by carbon particles, and least of all by normal rabbit brain. (f) It can be passed through Berkefeld (British) and Sietz (EK) filters.

The writer desires to thank the clinicians and pathologists at the Royal Infirmary of Edinburgh and of Glasgow, and at other institutions in Scotland and England, who so willingly co-operated in the investigations. He is greatly indebted to Drs. J. Duncan White and C. M. Scott for their assistance in connexion with the x-ray experiments, and to Professors Mackie and Drennan for their valuable advice and helpful criticism.

A new edition of the *Official Guide Book of Medical Post-Graduate Work in Hungary* has just been issued by the Hungarian Medical Post-Graduate Committee (VIII, Máriá-utca 39, Budapest). This excellently illustrated volume contains full details in English of the various hospitals and clinics where all kinds of medical post-graduate work can be undertaken. It is stated that all the professors and chief physicians speak English, French, or German. In addition to its main office in Budapest, the Post-Graduate Committee has subcommittees in the other university towns, and arrangements for study can be made wherever desired. Much modernization of the existing institutions has been effected in the last few years, and several new medical buildings have been erected. The *Guide Book* contains also information about places of historic interest in Hungary. There are now in that country four medical faculties, with 4,520 beds available for medical and post-graduate training, as well as 21,534 beds in the large public hospitals.

THE USE OF 2:4-DINITROPHENOL AS A METABOLIC STIMULANT

BY

D. M. DUNLOP, B.A., M.D., F.R.C.P.Ed.*

(From the Clinical Laboratory, Royal Infirmary, Edinburgh)

It has been known since 1885¹ that nitrated naphthols can stimulate metabolism, and during the war attention was called to their toxic effects owing to the incidence of poisoning among workers in munition factories. A review of these effects was made by Perkins,² and they were more recently commented on by the Council of Pharmacy and Chemistry of the American Medical Association.³ Only incomplete investigations of the pharmacological action of such compounds were, however, made till 1928, when Heymans⁴ and his co-workers revived interest in the subject by a series of publications which showed that certain nitrophenols are powerful stimulators of metabolism, causing a greatly increased oxygen consumption. When a considerable dose is taken the endogenous heat production may be so stimulated as to cause a rise of temperature, and death from a lethal dose occurs during a hyperpyrexia. The lethal dose of dinitrophenol for rats has been shown by Anderson, Reed, and Emerson⁵ to lie between 30 and 50 mg. per kilo of body weight, but doses as small as 5 mg. per kilo of body weight may produce pyrexia in man, and it has been stated that the margin between the febrile and fatal dose is narrow.

During the last two years Magne, Mayer, and Plantefol,⁶ and Cutting and Tainter,⁷ have published reports on the main pharmacological actions of dinitrophenol. All these workers are agreed that the action of the drug in stimulating the metabolic rate is peripheral, due to an increased oxygen consumption in the tissues, and is independent of nervous and glandular action. In considering the source of the fuel for the increased metabolism they are also agreed that the body proteins are not broken down to any appreciable extent. The French workers, however, observing in the experimental animal under the influence of dinitrophenol a marked decrease of the carbohydrate content of the body, particularly in respect of the liver glycogen, and a corresponding rise in the blood sugar, argued that the excess metabolism was mostly at the expense of carbohydrate. The experimental and clinical studies of Cutting and Tainter, on the other hand, failed to reveal any difference between the excess metabolism due to dinitrophenol and that occurring normally. The latter workers, using this drug in doses of 3 to 5 mg. per kilo of body weight, have recommended its use in the treatment of obesity, and have recently published encouraging results from extended clinical trials in which an average daily oral dose of 0.3 gram (5 grains) of the drug was administered to 113 consecutive cases of obesity without drastic dietetic restrictions. No severe cumulative or toxic effects were produced, though most of the patients noticed a sense of increased warmth and increased sweating, while in 7 per cent. of them a skin rash occurred, and in 5.3 per cent. there was a loss of taste. These side actions cleared up quickly, without sequelae, on discontinuing the medication. Anderson, Reed, and Emerson⁵ have also treated fourteen cases of obesity, using similar doses of the drug, and obtained some slight loss in weight without much dietetic restriction. In one patient, however, they obtained a serious allergic skin and joint reaction. This patient suffered from chronic articular rheumatism, and it is suggested that individuals suffering from this complaint have a lessened resistance to the agent. Indeed, Perkins,² in his review of the poisonous effects of dinitrophenol on

* In receipt of part-time grant from the Medical Research Council.

munition workers, reported that cases of chronic rheumatism, alcoholic addiction, diabetes mellitus, tuberculosis, and renal and hepatic insufficiency were particularly sensitive to it.

In addition to dinitrophenol, a related compound, dinitro-*o*-cresol, has been reported on by Dodds and his co-workers.⁸ They claim it to be considerably more active than dinitrophenol, and stress, as other workers have done in the case of dinitrophenol, that neither the pulse rate nor the blood pressure is raised in any way proportionately to the height of the metabolism. Dodds further states that toxic symptoms are occasioned by dinitro-*o*-cresol when the metabolic rate is raised by its means to over 50 per cent. above the patient's normal. He mentions particularly sweating, lethargy, headache, loss of appetite, and a greenish-yellow tinge in the conjunctivae. This latter symptom has also been noted by Tainter, using dinitrophenol, but neither worker discovered any excess bile pigments to be present in the blood of such cases; and it must also be remembered that the drugs themselves are dyes producing much the same colour as bile pigments.

The fact that drugs of this type have specific powerful effects in raising metabolism, without at the same time causing tachycardia, combined with their cheapness and availability, might strongly recommend them as superior to other metabolic stimulants in general therapeutic use. On the other hand, Dodds⁸ has suggested that in spite of their effects on metabolism such drugs do not act as a substitute for thyroid in hypothyroid states, except in so far as they may reduce excess body weight. Further, it has yet to be demonstrated that they are as safe and efficient for weight reduction in human beings as other methods in common use. It may indeed be argued that so many toxic reactions have been produced in the relatively small number of cases treated that the use of such compounds is not as yet clinically justifiable on a large scale, and that their popularization as weight reducers might well be disastrous. It is therefore of importance that careful pharmacological investigations and cautious clinical trials of these new and powerful products should be made before their widespread application is undertaken.

METHOD

The effects of 2:4-dinitrophenol on human beings, when administered orally in gelatin capsules, were studied over a considerable period of time under carefully controlled conditions in hospital. The subjects were three obese women. In Cases 1 and 2 the patients had normally mildly reduced basal metabolic rates, while Case 3 presented the typical features of advanced myxoedema. The drug was given to Case 1 in single doses of 2 mg. per kilo of body weight, several days being allowed to elapse between each dose. Metabolic readings were made before the drug was given, and at intervals of a quarter of an hour afterwards for two hours, and thereafter every morning until the metabolism had for some days returned to its normal base line. This procedure was repeated on four occasions. Case 2, after a considerable control period, was given dinitrophenol in doses rising from 1 to 3 mg. per kilo of body weight, the metabolism being allowed to reach a constant maximum for each quantity of the drug before the dose was increased. The effects were contrasted with those produced by a daily dose of 6 grains of thyroid. Case 3, after a similar control period, was given a daily dose of 3 mg. per kilo of body weight, and the effects again contrasted with those produced by 6 grains of thyroid daily, and also with those occasioned by 50 mg. of di-iodo-tyronine daily, a synthetic preparation reported on by Anderson, Harington, and Lyon.⁹

Throughout their stay in hospital the patients had their diets kept constant in respect of total calories and in respect of the content of fat, carbohydrate, and protein. With the object of giving the patients a diet just sufficient to maintain their weight while leading a sedentary life, without supplying material for luxur consumption, the diets for the three

individuals varied between 1,800 and 2,000 calories. Fluids were not limited. The patients were weighed daily at the same hour. The basal metabolism and respiratory quotients were determined daily, early each morning, using the Douglas bag and Haldane gas analysis apparatus, and all the determinations were made in duplicate. Twenty-four-hour specimens of urine were collected and measured daily, and were then examined for abnormal constituents, their total nitrogen content being estimated by the micro-Kjeldahl method. The pulse and blood pressure were noted daily under basal conditions, and the blood urea, sugar, cholesterol, and icteric index were frequently determined. A four-hour oral temperature chart was kept, and in Case 2, on three occasions, a continuous temperature chart, galvanometrically recorded by means of an electric thermo-couple strapped into the axilla, was kept for two hours before, and for twenty-two hours after, the administration of dinitrophenol.

BASAL METABOLIC RATE

In each case dinitrophenol was found to have a powerful effect in raising metabolism and in increasing oxygen consumption. The absorption of the drug was exceedingly rapid, a noticeable effect being produced on the metabolism a quarter of an hour after the oral administration of a single dose, and a maximum effect for the day being produced in an hour's time. This effect would last almost unimpaired for twenty-four hours, but in forty-eight hours the metabolism had invariably fallen to a level only slightly above its original value.

TABLE I.—Effect on Four Occasions of 2 mg. per Kilo, of Body Weight of Dinitrophenol on the Metabolism of Case 1

	I.	II	III	IV
Basal	- 16	- 9	- 14	- 15
½ hour after dinitrophenol	- 3	+ 7	± 0	- 3
1 hour	+ 2	+ 11	+ 10	+ 2
1 hour	+ 7	+ 21	+ 16	+ 7
12 hours	+ 4	+ 21	+ 14	+ 4
24 hours	+ 7	+ 8	+ 8	+ 7
48 hours	-	- 8	+ 1	-
72 hours	- 9	- 12	- 5	- 9

With the daily administration of the drug the metabolism rose rapidly on the first day, and on subsequent days continued to rise slightly. A maximum level was reached about the fourth day, at which point it remained, fluctuating within very narrow limits, till an increased dose sent it up still further, or the withdrawal of the drug brought it rapidly to normal. For all practical purposes the effect on the metabolism, even after prolonged administration, had worn off within seventy-two hours of the withdrawal of the drug. The rapidity with which the action of the drug on the metabolism wears off, and the rapidity with which its effects become manifest, are thus in marked contrast to the slow onset and slow subsidence of thyroid action, the effects of which only become apparent some three to four days after its administration is started, and continue for five to six days after it has been withdrawn.

The action produced by dinitrophenol was found to be fairly proportional to the dosage employed. In Case 1, where single doses of 2 mg. per kilo of body weight were given, the metabolism twenty-four hours later was invariably found to be increased by almost exactly 23 per cent. In Case 2, where different doses were employed, 1 mg. per kilo of body weight produced an average maximum rise in metabolism of 12 per cent., 2 mg. of 25 per cent., and 3 mg. of 35 per cent. In Case 3, where 3 mg. per kilo of body weight were given, an average maximum rise of 42 per cent. was produced.

URINARY NITROGEN AND RESPIRATORY QUOTIENT

Dinitrophenol exerted no significant influence on the excretion of urinary nitrogen. This contrasts with the very considerable increase in nitrogen excretion observed

TABLE II.—Effect of Dinitrophenol and Thyroid on the Excretion of Urinary Nitrogen

Average Urinary Nitrogen Excretion in Grams per Day.

	Case 1	Case 2	Case 3
Control period ...	9.44	8.56	7.89
Dinitrophenol period ...	9.00	9.09	8.61
Thyroid period ...	—	12.15	11.91

in patients undergoing treatment with thyroid, in which respect the cases under consideration were no exception. It is apparent, therefore, that the excess metabolism due to dinitrophenol is not conducted at the expense of exogenous or endogenous protein to any appreciable extent,

tion in the respiratory quotient, though our previous experience suggests that on the average the effect of thyroid is to raise the respiratory quotient slightly.¹⁰

These results would seem to indicate that the excess metabolism produced by dinitrophenol is conducted at the expense of fat rather than at the expense of carbohydrate or protein, though this interpretation is subject to the criticism that the method of approach is an indirect one. From the fact that no ketone bodies were ever discovered in the urine, it would seem that any fat used was completely and satisfactorily broken down.

PULSE AND BLOOD PRESSURE

No important increase in pulse rate or change in blood pressure was produced by dinitrophenol, a 40 to 50 per cent. increase in metabolism being associated with a pulse rate raised by less than ten beats per minute. These observations are in remarkable contrast to the well-known effects of thyroid on the circulation, which so often contraindicate its use in cases of obesity. In Case 3,

CHART I.—Effect of dinitrophenol and thyroid on Case 2.

CHART II.—Effect of dinitrophenol, thyroid, and di-iodothyronine on Case 3.

whereas a small but significant part of the excess metabolism produced by thyroid is due to protein.

Reference to Chart II shows that a considerable fall in the respiratory quotient occurred during the period of dinitrophenol administration to Case 3, the average basal respiratory quotient for the control period being 0.84, while on dinitrophenol the average was 0.74. Again, in Case 1, where frequent determinations were made during the two hours following the administration of single doses of dinitrophenol, a tendency for the respiratory quotient to fall was usually noted, and there was never a significant rise. In Case 2 the respiratory quotient remained remarkably low throughout the control period, and remained low during the whole period of dinitrophenol administration (see Chart I). In the present series of experiments the exhibition of thyroid caused no very significant varia-

tion for example, a metabolic increase of only 20 per cent. induced by thyroid resulted in the pulse rate being accelerated by twenty-four beats a minute, and caused the patient to complain of palpitation. This constitutes a distinct advantage of dinitrophenol over thyroid extract or thyroxine, but in one respect it is a drawback, since no conception of the extent of the metabolic increase can be gauged from the state of the pulse; and the only methods of evaluating the metabolism under dinitrophenol are by resort to the somewhat cumbersome procedure of determining the basal metabolic rate, or by relying on the subjective sensations of the patient, which may on occasion give an erroneous impression. Di-iodothyronine, which in all other respects appears to produce the same metabolic and endocrine effects as thyroid, seems to have a less severely disturbing influence on the circulation.

WEIGHT

TABLE III.—Average Effect of Dinitrophenol and Thyroid on Weight in Kilos per Week

	Case 2	Case 3
Control period	Loss of 0.70	Gain of 1.33
Dinitrophenol period ...	Loss of 0.84	No change
Thyroid period	Loss of 1.47	Loss of 2.10
Di-iodothyronine period ...	—	Loss of 0.77

It will be seen that the weight loss produced by dinitrophenol was exceedingly disappointing, and that the great increase in metabolism which it occasioned was associated with a loss of weight quite insignificant in comparison with that produced by thyroid, in spite of the fact that the metabolism was not raised to anything like the same extent by the latter. This disparity in results can only be explained by the fact that thyroid exercises a marked effect on the partition of water in the body, whereas dinitrophenol is ineffective in this respect, in spite of the considerable sweating which it induces. Indeed, the actual loss of weight under dinitrophenol approximated closely to the loss calculated from the metabolic results on the basis that no change in water balance occurred. A comparison of the percentage of average urinary output to intake during the control, dinitrophenol, and thyroid periods gives suggestive results.

TABLE IV.—Effect of Dinitrophenol and Thyroid on the Average Percentage of Urinary Output to Fluid Intake

	Control Period	Dinitrophenol Period	Thyroid Period
Case 2	66 per cent.	62 per cent.	83 per cent.
Case 3	87 ..	74 ..	102 ..

In a previous comparison of the therapeutic effects of diet and thyroid in the treatment of obesity we have shown that approximately 9 grains of thyroid daily are required to cause a fall in weight equivalent to that produced by treatment with a diet of 1,000 calories¹¹—a dosage seldom tolerated by the obese patient. Since thyroid is itself, apparently, a very much more efficient weight-reducer than dinitrophenol, it would appear that exceedingly toxic or even lethal doses of the latter would be required to ensure the same effect as that produced by diets of 1,000 calories.

OTHER EFFECTS

As long as the metabolic increase effected by dinitrophenol was not more than 30 per cent. above the patient's normal the subjective sensations experienced were not unpleasant. Indeed, with small increases in metabolism a rather pleasurable sensation of comfortable warmth was produced. With a greater elevation, however, uncomfortable symptoms of heat and sweating were experienced, and with a rise of over 40 per cent. the patients were considerably distressed by these effects, and complained of lethargy and exhaustion. Notwithstanding this, no significant elevation of the temperature was noted on any occasion, even when this was continually recorded over a period of twenty-four hours by a sensitive electric thermo-couple strapped into the axilla. Apparently it was therefore possible, with the doses used, for the endogenous heat production to be satisfactorily dissipated.

Apart from the symptoms mentioned, no toxic effects were occasioned by dinitrophenol, and the palpitation, invariably experienced by the patient in Case 3 when given thyroid, was noticeably absent while she was receiving this drug. An insignificant increase in the blood sugar occurred under dinitrophenol, while there was a similar insignificant increase in the blood urea under thyroid medication. The blood cholesterol and icteric index were unaffected, and no abnormal contents were produced in the urine.

In spite of its effects on metabolism dinitrophenol is apparently no substitute for thyroid. Case 2 was just as

myxoedematous, with a basal metabolism of +18, the result of nearly three weeks' treatment with dinitrophenol, as she was previously with a basal metabolism of -30. On the other hand, small doses of thyroid, thyroxine, or di-iodothyronine, sufficient to raise the patient's metabolism to a figure no higher than -10, speedily improved her myxoedematous symptoms and appearance.

CONCLUSIONS

Dinitrophenol is a powerful and rapidly acting stimulant to oxidative metabolism, which does not at the same time upset the pulse rate or the blood pressure. The excess metabolism, which subsides rapidly when the drug is withdrawn, is conducted largely at the expense of fat. In doses of 3 mg. per kilo of body weight it may increase the metabolism to as much as 50 per cent. over its original level, though the average increase is usually less than this amount. No serious toxic effects were produced by such a dose in the present investigation, though such are recorded in the literature. Uncomfortable sensations of excessive warmth, sweating, and lethargy may, however, be complained of, which may necessitate the average dose being less than 3 mg. per kilo of body weight. In such doses dinitrophenol is likely to be singularly ineffective in lowering excess body weight, and even in maximum therapeutic doses it does not compare, as a weight reducer, with thyroid, and still less with dietetic restriction. It is no substitute for thyroid in myxoedematous states.

I am indebted to Professor D. M. Lyon for the opportunity of carrying out this investigation.

The Import Duties (Drawback) (No. 2) Order, 1934, issued by the Treasury on March 8th on the recommendation of the Import Duties Advisory Committee, provides, under Section 9 of the Finance Act, 1932, for the allowance of drawback of customs duties for a period of twelve months in respect of castor seed used in the manufacture of exported castor oil. Following the imposition in March, 1932, of the general *ad valorem* duty on castor seed there has been a great reduction in the imports of foreign seed into the United Kingdom, and it is represented that the removal of the British buyer from the market has materially contributed to the fall of the world price of foreign seed to a level which gives the foreign seed crushers an advantage over British crushers in the export markets for castor oil. The granting of drawback will substantially restore to the British crushers economic freedom in the choice of seed required for their export trade in castor oil, which in 1933 amounted to nearly £250,000. A White Paper containing the Treasury Order and the Advisory Committee's recommendation is published by H.M. Stationery Office (Cmd. 4532).

HEREDITY AND VARICOSE VEINS

BY

CONSTANCE OTTLEY, B.M., F.R.C.S.

ASSISTANT SURGEON, NEW SUSSEX HOSPITAL FOR WOMEN

It has long been recognized that heredity is one of the factors in the causation of varicose veins. It is, however, a matter of particular difficulty to obtain exact evidence of its influence in a given case. Varicose veins are so common, and the symptoms to which they give rise are often so trivial, that they are less prone to attract attention than are rarer hereditary conditions. This applies especially to the older generations; among younger people, as a result of present-day fashions in dress, sport, etc., varicose veins are much more likely to be noticed and treated. For this reason a positive family history, especially as regards the older members of the family, is of greater weight than a negative one; and it must not be concluded that a hereditary factor is not present

FIG. 1.

FIG. 2.

because a patient thinks that none of his ancestors had varicose veins.

The comparatively uninteresting character of the complaint, and the difficulty of obtaining evidence of its hereditary nature, may account for the fact that the literature of the past ten years contains but scanty reference to the subject. Nobl and Remenowsky¹ emphasize the importance of a hereditary factor, but give no examples. F. Curtius² gives one family tree extending over four generations, and including seventeen sufferers among a total of fifty-eight individuals, and two other less striking pedigrees. Jensen³ questioned 354 patients suffering from varicose veins, and obtained from 56 per cent. the statement that some other member of the family was also affected. No detailed pedigrees are given.

This paper is based on a series of fifty cases under treatment for varicose veins. Of these patients fourteen stated that they knew of no other cases in their respective families. The remaining thirty-six patients can be divided into two groups.

1. The inheritance of varicose veins appeared to be of a simple dominant type in twenty-six families, of which three instances may be given (Figs. 1, 2, and 3).

2. In ten families varicose veins had occurred in one or more members of a sibship, and the parents were believed to have been unaffected. In all these cases the testimony of the parents themselves was not available, owing to death or other reasons. In the cases where only one member of a sibship was affected, and in several other instances (four families in all) one or more uncles or aunts had varicose veins. In two of these families the condition had appeared in one of the grandparents—that is, it had skipped a generation.

There are two possibilities here. Either a recessive factor is concerned, or the more usual dominant type of inheritance is masked by the failure of the disease to become manifest—owing to absence of some other essential condition—in a predisposed individual.

The ten families above mentioned included eleven sibships (there were two sibships in one of the families) in which cases of varicose veins occurred, the parents being unaffected. The total number of individuals in these sibships was eighty-two, of whom twenty-three had varicose veins and fifty-nine were unaffected. This gives a percentage of affected persons of 28—a higher figure than would be expected if the defect were a recessive one—but the numbers are too small to carry much weight.

FIG. 3.

FIG. 4.

One of these pedigrees is given in Fig. 4.

Here, if the defect is a recessive one, it is necessary to assume that both wives in the P generation, as well as the man, were bearers of the recessive factor. This seems an unlikely assumption, especially as the wives are not known to have been related to one another. It appears much more probable that the predisposition was present in the father of the family, but failed to become manifest.

Two new series of brochures, numbering 316 to 323 and 324 to 332, have been issued by the International Labour Office. The former deals with parasites, petroleum and lubricating oils, phosgene, photographic industry, plaster, plastic earths, printing trades, and quinine; and the latter with rice-field workers, scavengers and road makers and menders, silicon, silk, skin diseases, social welfare, soldering, etc., soot, and sport (hygiene and physiopathology). Subscribers desiring to bind their brochures are informed that these issues complete the subjects coming under the letters "P," "Q," and "R."

MEDICAL ASPECTS OF METHYL CHLORIDE

BY

ARTHUR P. GORHAM, M.B., CH.B.

HONORARY SURGICAL REGISTRAR, BRISTOL GENERAL HOSPITAL

British medical literature contains few references to methyl chloride, and only brief mention is made of it in textbooks on toxicology. This substance is of interest to the medical profession for several reasons: (1) on account of its toxic properties; (2) the symptomatology of poisoning by it is varied and liable to be overlooked and to be ascribed to other causes; (3) it has an extensive use as a refrigerant: it has been so used for many years, chiefly on the Continent and in America. Owing to the recent extension of the use of domestic refrigerators in this country methyl chloride is now in common use here. On land, installations are to be found in hospitals; hotels, and in a large number of shops, more especially in those of butchers, fishmongers, and grocers. In one new building in London over seventy machines are in use. One firm among several manufacturers of these plants has supplied over seven thousand installations in this country. It is therefore possible that toxic cases may be more frequent than formerly. The object of this paper is to set out the available information and to place on record a fresh case of poisoning.

Methyl chloride was discovered by Peligot and Dumas in 1835; it has the chemical formula CH_2Cl_2 , with a molecular weight of 50.474. It is a non-corrosive gas, and is usually supplied compressed into cylinders. It is colourless both in the gaseous and in the liquid state. The boiling point is -24°C . It possesses only a very faint, sweet, chloroform-like odour, and is non-irritating to the eyes and to the respiratory tract.

REFRIGERANT PROPERTIES

In medical practice it is used as a local analgesic in cases of neuralgia and neuritis, when it is sprayed on the affected part, producing intense cold by evaporation. Its inhalation causes narcosis, and this property was investigated in 1879 by a committee of the British Medical Association, who used an alcoholic solution, and reported a mild narcotic effect.

Commercially, as stated above, it has extensive use as a refrigerant, and it is reported from America that there are 75,000 domestic plants in use in one city. It was used as early as 1895 in the French Navy, and is now to be found in a great number of British mercantile ships. It may be of interest to enumerate some of the advantages this substance possesses as a refrigerant as compared with the more usual agents such as CO_2 , SO_2 , and NH_3 , from a list made by J. B. Churchill.

- (a) It is non-corrosive to metals used in refrigerating systems, and does not decompose into a corrosive when it comes into contact with moisture accidentally introduced.
- (b) It does not form an explosive mixture with air under ordinary conditions, and is stable at any temperature in the system.
- (c) It is only moderately inflammable, and is of relatively low toxicity compared with some other refrigerants.
- (d) It decomposes when in contact with an open flame, but yields no toxic substance.
- (e) It is non-irritating to the eyes and lungs, enabling servicing of equipment to be carried out without annoyance to persons occupying premises where it is in use.
- (f) It does not injure foods, flowers, or textiles when they are exposed to its vapour by leaks.

These properties account for the popularity of methyl chloride as a refrigerant. The dangers of fire or explosion

are small. The main consideration is the danger to the life and health of human beings. This arises (apart from the question of exposure during manufacture incurred by workers in the industry) from leaks in domestic or other plants, owing to the fact that its odour is so slight as not to be noticeable. In this connexion it is interesting to note a proposed patent in which aldehyde shall be added so as to produce a lachrymatory effect, thus indicating slight leaks.

TOXIC EFFECTS

Toxic effects are produced usually by unnoticed leaks taking place in enclosed or ill-ventilated places. If the leak is a slow one and the gas becomes diffused and diluted in the atmosphere its existence may never be appreciated; but at higher concentrations toxic symptoms arise. A concentration of 10 to 20 per cent. is said to be anaesthetic. The gas is slowly excreted, so that the effects of small amounts may become cumulative and cause symptoms only after some days.

It is considered by one German observer that individual susceptibilities occur. The following is the report of a case which came under my own observation.

On October 26th, 1932, several men were working in the cold store in the fore part of a ship. A small supply pipe of the methyl chloride refrigerating plant was accidentally broken across, allowing the escape of gas for about thirty minutes before the break was seen and plugged. No ill-effect was noticed by any of the men until five hours later. F. A., aged 40 years, felt sick and giddy, and noticed a mustard-like taste in his mouth. He went home, and was violently sick all night. The following day he was admitted into a local hospital in a state of collapse, with pallor and slight cyanosis. He felt giddy, and had a burning sensation in his mouth and throat. The pulse was 80 and the temperature normal. Vomiting ceased in twenty-four hours, and in three days he was discharged, normal in all respects. He resumed work, and is now in good health. The space in which these men were working was an enclosed one, ventilated by an open-top hatch with no through current of air. One other man had slight sickness and giddiness, but did not cease work.

In recent years nearly a hundred cases have been reported from abroad. Gerbo, in 1914, gave a record of two cases in ice machinists, and in 1923 Roth reported a further ten cases from Germany. In 1921 Schwartz recorded one fatality in ten cases among workers in the industry. Baker notes twenty-one cases with no deaths from America; and in Chicago, since 1928, twenty-nine cases are reported with ten deaths. Several isolated cases have been noted from European countries, with one fatality. The onset of symptoms is gradual in the milder cases; but in those of greater severity unconsciousness may be present at the commencement, and is usually accompanied by convulsions and delirium.

CASES ILLUSTRATING A MILD ATTACK

I am able to record four cases reported to me from this country illustrating the symptoms of a mild attack.

Case 1.—A young man while doing research work inhaled concentrated gas in an enclosed chamber. His main symptom was violent vomiting. As he developed nothing further he returned to work after a week, and is now in good health.

Case 2.—A fitter liberated a large amount of gas into an unventilated space in which he was working. He became violently sick with nausea, but returned to work in three days, having recovered.

Case 3.—A workman on a ship, while repairing some leaking joints, remained tightening them up for several hours in a badly ventilated space. He had violent sickness and nausea, and was well in six days.

Case 4.—While a vessel was at sea an engineer liberated most of the charge into a confined space without ventilating it, and had severe vomiting, but made a good recovery.

SYMPTOMATOLOGY

The symptoms as collected from various records may be stated to be as follows.

The onset is one of progressive drowsiness and apathy, going on to stupor, with nausea, vomiting, and abdominal pain. Muscular tremors may be present, and may be followed by tonic convulsions with marked cyanosis. Ocular signs and symptoms may be prominent. The pupils are usually dilated. Ptosis and nystagmus have been noted, also amblyopia. The temperature nearly always rises, and deaths with high pyrexia have occurred. The pulse and respiration rates are increased.

Renal Symptoms.—Anuria lasting twenty-four to forty-eight hours is usual in the more severe cases, and albuminuria occurs in about 50 per cent. The urine has always been found to be acid, and acetone and diacetic acid may be present. Baker observed formic acid in his cases, but other observers have not found this to be the universal rule. Hyaline and granular casts are sometimes seen.

The blood pressure is lowered, and the blood picture is one of primary anaemia, with a moderate leucocytosis. The cause of death is apparently respiratory paralysis. Sequelae have been noted, and chiefly affect the nervous system: ataxia, insomnia; vertigo, and dim vision, which persist for some months. Post-mortem examinations were performed on the fatal American cases, and the main findings consisted of petechial haemorrhages in the pleura, epicardium, and endocardium. Marked congestion of the lungs and kidneys was found, as well as early fatty changes in the liver. Chemical examination was negative.

DIFFERENTIAL DIAGNOSIS

The diagnosis rests on a history of exposure to the gas and on the symptoms detailed above, the predominating symptoms being nausea and vomiting, with drowsiness and a confused mental state of several days' duration.

The condition has chiefly to be distinguished from food poisoning, in which diarrhoea might be expected to be a more prominent symptom, and, in the case of botulism, consciousness to the end. The case recorded by me was thought to be one of coal-gas poisoning. Carbon monoxide poisoning shows a subnormal temperature, and has the spectroscopic bands of carboxyhaemoglobin in the blood. Poisoning by the heavy metals must be considered, and the evidence sifted in the absence of a clear history. Certain diseases of the nervous system, particularly encephalitis and meningitis, enter into the differential diagnosis. In this connexion it is of interest to note that the cerebro-spinal fluid in methyl chloride poisoning is fairly normal, especially the cellular content, but has been found under pressure in a few instances.

TREATMENT

The treatment of the condition consists, first, in getting the patient into the fresh air and in commencing the early administration of oxygen. Alkalis should be given freely. It may be necessary to control convulsions, but on no account should chloral or chloroform be used for this. As a powerful cardio-respiratory stimulant coramine in large doses is indicated. The patient should be kept in bed until the temperature and pulse are normal and all acute nervous symptoms have abated. The anaemia may have to be treated. The gas is oxidized slowly, and the aim of the treatment is to hasten oxidation.

SUMMARY

1. Attention is drawn to the increased use of methyl chloride as a domestic refrigerant.

2. The signs and symptoms of poisoning and observations gathered from several observers are described.

3. A case occurring in this country is placed on record and the different diagnosis is discussed.

A bibliography is appended from which further information can be derived.

Clinical Memoranda

RELATION BETWEEN EPILEPSY AND
CONGENITAL SYPHILIS

The following is a report of a pedigree which appears to be of some interest from the point of view of the much-discussed relation between epilepsy and congenital syphilis. Much has been written on the subject, and very divergent views expressed. Some authors go so far as to say that all cases of "idiopathic" epilepsy are ultimately traceable to syphilis, while others suppose, on the other hand, that there is no connexion whatever, and that any apparent relation is merely a coincidence. Mott,¹ for instance, says: "Because there are stigmata of syphilis on the body of a juvenile epileptic it does not necessarily follow that there is a causal connexion . . . it may be coincidence." He says also: "The question whether syphilis of the parents can modify the germ-plasm so as to render it biologically unstable, whereby a slight excitation suffices to produce a fit . . . is one that cannot be satisfactorily answered."

The weight of opinion is in favour of the view that congenital syphilis may result in pathological and local changes in the brain responsible for epileptic attacks, and that it may also so influence the germ-plasm that epilepsy results, even when the affected individual shows no other signs of congenital syphilis.

DESCRIPTION OF PEDIGREE

First Generation (I):

1. Male, 60 years. Denies syphilis. Has history of phthisis. Wassermann and Meinicke negative.
2. Female, 58 years. Wife of above. Had course of injections six years ago. No history of infection. Wassermann and Meinicke strongly positive.

Second Generation (II):

1. Male, 32 years. Always healthy. Has hypospadias, otherwise normal. Married six years; no children. Wassermann and Meinicke negative.
2. Wife of above. Healthy.
3. Male, 30 years. Always healthy. Married four years; one child; no miscarriages. Wassermann and Meinicke negative.
4. Wife of above. Healthy.
5. Male, 28 years. Always healthy. Married seven years. one child; no miscarriages. Wassermann and Meinicke negative.

6. Wife of above, 26 years. Always healthy. Wassermann and Meinicke negative.

7. Male, 25 years. Congenital syphilitic, with definite stigmata and much scarring of throat following ulceration of palate. Has had epileptiform convulsions since the age of 16 years. Wassermann and Meinicke strongly positive. Spinal fluid normal.

8. Female, 23 years. Always healthy. Wassermann and Meinicke negative.

9. Female, 20 years. Has received treatment by injection for congenital syphilis. Now in sanatorium for phthisis.

10. Male. Died at birth. Cause unknown.

Third Generation (III):

1. Female, 12 months. Child of II 3 and II 4. Healthy.

2. Male, 6 years. Child of II 5 and II 6. For the past year has had attacks of petit mal daily, with less frequent convulsive seizures. Has become increasingly difficult to manage. No signs of congenital syphilis. No neurological signs. Wassermann and Meinicke negative. Spinal fluid negative.

DISCUSSION

Case II 7 shows a combination of congenital syphilis and epilepsy; the relation of the two presents the same problems as other reported cases. But in this pedigree the child in the next generation, III 2 (a nephew), suffering from epilepsy alone, throws additional light on this case. III 2, though the grandson of a syphilitic, is born of parents who show no sign of the disease. While the occurrence of third-generation syphilis seems fairly well established (see the work of Nabarro² on the subject), all three generations appear always to be undoubtedly affected. Hence, there seems no reason whatever for considering this child a congenital syphilitic. An additional point in favour of this view is the likelihood that the grandmother contracted syphilis after the birth of the child's father (II 5).

To return to the second generation. We have here two congenital syphilitics (possibly II 10 also); one of them is an epileptic as well. That congenital syphilis is in any way an important factor in the causation of epilepsy in the last case is unlikely, in that it does not necessarily result in epilepsy in this family, nor is it necessary for its occurrence, as the case of "idiopathic" epilepsy shows. It seems justifiable to assume, therefore, that this pedigree provides a case in which the occurrence of congenital syphilis and epilepsy is certainly a coincidence.

I wish to thank Dr. Mapother for permission to use cases at the Maudsley Hospital.

Medical Officer, Maudsley Hospital.

A VERY RARE CAUSE OF SUDDEN DEATH

Below are given particulars of a case of scarlet fever complicated by measles, in which the child was completely convalescent from these diseases, having been three months in hospital, and then suddenly collapsed and died. The cause of death is, I believe, so exceedingly rare as to be perhaps unique in such a case, and I hope that this notice will elicit from superintendents of other fever hospitals comment as to similar cases they may have seen.

J. B., a girl aged 5, was admitted to the Woodbridge Isolation Hospital, Guildford, on November 20th, 1933, as a case of scarlet fever. She had commenced illness on the 17th with a sore throat and a temperature of 103° F., and

had a rash on the 19th. On admission there was a faded rash, mottling of the skin and flanks, tongue slightly papillated, and fauces slightly red. On admission 5 c.cm. B.W. scarlet fever antitoxin was given intramuscularly. On December 6th she had a rise of temperature to 99° and a well-marked typical general scarlet rash. The temperature was normal on the following day. On December 16th it went up to 100.8°, the child having developed an acute cold in the head. Temperature was maintained until the 21st, when a right cervical adenitis developed. On December 25th it rose to 102°, and all signs of measles developed. (This infection was due to a cross-infection arising in the ward.)

By December 31st the temperature had dropped, and conditions seemed satisfactory. On January 3rd right otorrhoea developed, and on the 5th the left ear commenced discharging, as did the nose. Nose and ears continued to discharge profusely for some time. On January 23rd the nose was dried up and the ears discharged less. On January 27th swelling and fluctuation developed at the back of the right ear, the skin was incised, and some superficial pus evacuated. This caused a rise of temperature to 100° for one day. The temperature immediately subsided on the pus being let out.

The child had been up and about since January 10th, and was only kept in bed on the 26th and 27th for the rise of temperature due to the superficial pus. Progress then appeared entirely satisfactory, the ear incision healing well, and the discharge from ears lessening. The onychia of the left thumb, which had caused some trouble, was also healing well. On February 10th she was playing about all day, but vomited once in the evening. This was thought to be due to some cake she had eaten. At 4.30 a.m. on the 11th the child appeared to be sleeping normally; an hour later she was collapsed, unable to lift herself, and complained of a headache. She was completely conscious—eyes normal, no sign of paralysis—but the pulse was imperceptible. She died at five minutes past six.

POST-MORTEM EXAMINATION

The post-mortem examination was made by Dr. R. C. Matson, pathologist, Royal Surrey County Hospital, Guildford, who reports as follows.

Head and Brain.—The dura is stretched tightly over the hemispheres, and on incision there is an escape of excess of cerebro-spinal fluid, which is obviously under tension. On reflecting the dura the vertex of the brain is very oedematous, and the vessels are markedly congested and injected. The brain substance actually "pits" on pressure, and there is slight though definite thickening of the pia-arachnoid on the vertex and also at the base of the brain. *No pus is to be found anywhere.* There is a small plaque of loose bone from the outer table just external to the auditory meatus. A large portion of the right petrous part of the temporal bone was removed, but no dead bone is found. The base of the brain is very congested and also oedematous. No meningitis.

Thorax and Viscera.—Oesophagus and trachea are normal. No enlarged glands in the thorax at all. Heart shows no abnormalities; nil in pericardium. Lungs show some congestion at each base behind, but this is probably only hypostasis, and is not pathological. No pleurisy or pericarditis.

Abdomen and Viscera.—Liver is rather congested, but substance is pale. Kidneys both quite normal. Spleen slightly enlarged, with prominent Malpighian corpuscles. No perisplenitis. Stomach and duodenum are normal. Gall-bladder normal, no stones anywhere.

Conclusion as to Cause of Death.—Acute cerebral oedema, mostly at vertex, but extending on to base of brain and to a lesser extent into the cerebellum. Fourth ventricle somewhat dilated, but lateral ventricles are not. This caused considerable increased intracranial pressure (vide the tightness of the dura), with involvement of the respiratory centre in the nature of a paralysis. It is possible that there had been some oedema and increased vascularity for a little time, and the sudden rise in pressure was the final act. There was remarkably little to show that the otorrhoea had anything to do with it.

F. A. BELAM, M.D.,

Medical Superintendent, Guildford, Godalming,
and Woking Joint Hospital Board.

Reviews

ARTHROPLASTY

Professor ERWIN PAYR of Leipzig reminds us, in the introduction to the first part of his grandly planned work on Stiff Joints and Arthroplasty,¹ that books have their destinies. He intended, when he first began it, to write on the technique of operations for the relief of stiff joints, but soon found himself constrained to do a great deal more, so that it has come about that the 880 large octavo pages of the volume now under notice constitute only the "First Part," and are taken up with consideration and discussion of the pathology and biology of joints, the pathogenesis and pathological anatomy of ankylosis, clinical considerations, diagnosis, and indications for treatment.

Many years' occupation with ankylosis and everything connected therewith taught the author that the preliminary subjects treated in this volume are extraordinarily attractive, and in particular is it necessary to work out the indications for treatment, for in the right selection of cases lies mostly the secret of good results. We have to occupy ourselves with the definition of ankylosis, with its results, especially as regards disorders of growth in the young. Study of muscle tone and its influence on joint pathology must be worked out on modern lines. Relapse or loss of a part of the mobility gained, whether through incomplete regeneration or otherwise, is a problem by itself. The material furnished by operations is continually increasing, and as far as it gives anything new it must be introduced into this work. Moreover, it is necessary to distinguish sharply between ankylosis caused by trauma in an otherwise healthy subject, and the result of systemic disease such as arthritis, the treatment advisable in the two categories being widely differentiated. Professor Payr gives clear definitions of ankylosis and of arthroplasty, and insists on the importance of the distinction between obstacles to movement such as bony prominences and true ankylosis. The failures of arthroplasty may vary between flail-joint and re-formation of ankylosis. Among the ankyloses of various parts of the human frame those of the vertebrae are in a class by themselves.

In his opening chapter Professor Payr gives a brief outline of the history and development of arthroplasty, which, he says, is a century old. The manifold attempts made are indications of the difficulties of the pre-antiseptic days. Early operations were both bloodless (that is, subcutaneous) and bloody. The first for ankylosis of the hip was the subcutaneous osteotomy of William Adams of London, but small joints had been attacked much earlier—for instance, that of the lower jaw by Berard in 1838. Dieffenbach excised a wedge, as did Rochet, Esmarch, Rizzoli, and Humphry. For twenty years this remained the method of choice. In 1880 Julius Wolff introduced his operation of arthrolysis, freeing the joint subcutaneously with a chisel, and afterwards maintaining movement. He reported four cases of fibrous and five of bony ankylosis. His cases were mostly in the elbow, but he showed thus the possibility of restoring motion. Verneuil recommended the use of a cap of muscle over the divided bone in a case of stiff jaw, but the decisive stroke was struck by Hellerich in 1893, when he performed such an operation, and in 1905 he carried out what Payr calls a real arthroplasty. After that "stroke upon stroke" was struck by Nelaton, Duval, Murphy, and Hoffa, using pedunculated muscle, aponeurosis, or fat flaps. Murphy of Chicago made a new departure, especially in arthroplasty of the knee. His first knee case was done in 1902. He made many experiments

on animals, and went deeper than his foregoers into biology, anatomy, and physiology.

Payr claims to have been the first in Europe (in 1910) to attain a fully satisfactory result in a knee-joint, with movement to a right angle and full and secure function. He generally improved technique. His work included biological researches, and he showed in animals that there was an astonishing power of regeneration of joints and such parts as capsules and ligaments. Payr's pupil, Sumita, carried such investigations further on a large scale. Many attempts at transplantation of joints have been attempted on animals, but only in the case of small joints has success been attained (Oehlecker). The material offered by the World War was ample, but on the other hand it was generally infected. During recent years there has been a tendency to revert to simple arthrolysis. Professor Payr insists on the importance of publishing full details of all cases of arthroplasty, whether successes or failures. Sure conclusions cannot be drawn from a few cases, but only a few surgeons have much experience.

Surgeons of all nations have taken part in building up arthroplasty. The Americans, French, and Germans have made good beginnings. The Americans particularly have made researches on animals. The English have been remarkably backward, and so also the Italians, with the exception of Putti and his school. "The Germans have done most. It can be denied with difficulty that the Germans have struck the decisive blows." This display of surgical chauvinism is not surprising in a people who are anxious to reassert themselves, and its injustice to the claims of some other nations will no doubt be passed over by the countrymen of Murphy and Willis Campbell and McAusland.

We have dealt at some length with the first chapter on account of its historical interest. In the remaining nine chapters of this first part Professor Payr discusses in considerable detail the history of development and comparative anatomy of joints, classification of ankyloses and pathology, and physiology of the same, biology of nearthroses, arthroplasty in animal experiments, the clinical aspects of ankyloses, the diagnosis of their causes, the research methods in the service of diagnosis, such as x rays, and indications for operations and treatment. There are many illustrations, some of them in colour. If the second volume is to be on the same scale, we shall have a very full statement of Professor Payr's opinions and experiences and what should be a valuable guide to the practice of arthroplasty.

RADIUM AND X RAYS IN GYNAECOLOGY

The application of radium and x rays to the treatment of malignant disease aroused great hopes, many of which were incapable of fulfilment, and thus caused at the same time a certain amount of disappointment and distrust. Patients already have that little knowledge about radiotherapy which may be so dangerous, and the practitioner is not infrequently doubtful whether or not treatment by radium or x rays should be advised. Dr. MALCOLM DONALDSON has given him much help in a very useful little handbook² wherein he sets out simply, lucidly, and authoritatively the present position occupied by the various radiological methods of treatment for the diseases peculiar to women. Dr. Donaldson starts with some introductory remarks on the physics of radium and x rays. These are so clearly set out that any reader can follow them and most readers will profit from them. He continues with a survey of the effect of radium and x rays on living cells, steering his way effectively through the conflicting theories which are still held on this subject.

¹ *Gelenksteifen und Gelenkplastik*. Von Professor Erwin Payr. Erster Teil. Berlin: J. Springer. 1934. (Pp. 880; 240 figures. R.M. 120; geb., R.M. 124.80.)

² *Radiotherapy in the Diseases of Women*. By Malcolm Donaldson, M.B., F.R.C.S. London: Hodder and Stoughton, Ltd. 1933. (Pp. 131; illustrated. 7s. 6d. net.)

The third chapter explains the various methods by which radium can be applied and the factors concerned in dosage. Dr. Donaldson is an earnest believer in periodical examinations, and he pleads eloquently for the education of the public about cancer and its treatment. He has had bitter experience of cancer terror and of that extremely foolish attitude in medical men which ridicules a patient for suffering from such a fear. He argues that education in tuberculosis and the significance of cough and haemoptysis has played a large part in the improved statistics of pulmonary tuberculosis and has certainly done the population no harm.

The author then sets out the various morbid conditions, malignant and non-malignant, of the uterus and its appendages, explaining briefly the pathology and diagnosis, and deals with the treatment of each of them. Although he is an enthusiast for radiological methods, he holds the scales very fairly, and admits that certain conditions cannot be treated by these means. He points out the enormous advantage gained by a patient whose disease can be treated either while she goes about her work, or at most with a week in bed, over another patient with the same condition who has to face the terrors and horrors of a major surgical operation with confinement to her room for several weeks. Granted that the results of radiotherapy are as good, there seems no doubt that it is the preferable method. Dr. Donaldson gives a number of statistics to show that in cancer of the cervix and other lesions surgery can claim no advantage in results.

The book is very pleasantly produced; it is light to handle and the type is clear. There are a number of diagrams in the text and some plates; a coloured illustration shows the practitioner the warning red spot on which he should at once suspect cancer of the cervix at a stage when it can be effectively eradicated. Dr. Donaldson's style is clear and easy to read. The text is conveniently divided by side-heads, and there is an excellent index. We cordially recommend this useful little work to every general practitioner and medical student.

PROGRESS IN PSYCHIATRY

It is gratifying to find that one of the best of Messrs. Churchill's Recent Advances Series¹ has met with such a widespread appreciation that a second edition is called for within a comparatively short space of time, when it is remembered that psychiatry is a subject which cannot appeal to the whole of the medical profession. The first edition has already been favourably noticed in these columns, so that it is only necessary to draw attention to the improvements and additions, opportunity for which has been afforded to Dr. HENRY DEVINE in the present volume.

On the subject of germinal inheritance in the psychoses, attention is properly drawn to the errors of Mott's conclusions with regard to anticipation in the light of more thorough examination of the material. The conclusions as to the influence of heredity upon psychoses are somewhat conflicting, but there seems no doubt that it is important, especially in regard to the manic-depressive reaction. The type of psychosis transmitted, although frequently similar, is not always so, and there seems to be a tendency for the dementia praecox type to appear from any tainted stock. The apparent constitutional affinity between psychosis and tuberculosis is discussed, also the relationship of pernicious anaemia to psychoses is dealt with, and the conclusion comes to is that the former acts as a precipitating or aggravating agency rather than in strict causal relationship. Reference is

made to the interesting recent work on deficient oxygenation of cerebral and other tissues in relation both to narcosis and to dementia praecox. This comprises the actual new matter in this edition, but other sections are brought up to date by reference to new statistics and investigations in various branches, especially in relation to the toxic psychoses and to malaria therapy.

An interesting review of recent literature on the subject of the application of psycho-analysis to the psychoses confirms the generally held opinion that, however interesting a study this may afford, its therapeutic value is slight. With regard to the analysis of children, while not accepting all the conclusions of Melanie Klein, there can be no doubt as to the importance of investigation of the very earliest stages of the psychoses, and therefore an investigation of abnormal psychological reactions in the first decade of life ought to be encouraged. All those in any way interested in psychiatry who do not possess this book should certainly acquire the present edition, and those who are already acquainted with it will find much of additional use in its expanded and rearranged form.

POISONOUS FUNGI

In a monograph entitled *Le Poison des Amanites Mortelles*² R. DUJARRIC DE LA RIVIÈRE describes agaric poisoning in all its aspects. A full botanical description is given of the various toxic species of the agaric fungi, of which the best known is fly agaric (*Amanita phalloides*). The description is amplified by some beautiful coloured plates. The author describes in sequence the chemical properties of the poison, its pharmacological action, and both the clinical symptoms and the pathological signs of intoxication. He then takes up the medico-legal aspect of agaric poisoning, and this part of the book includes a full description of the histology of the spores of twenty-nine species of fungi, this description being amplified by a series of plates. Finally, the author discusses the treatment and prophylaxis of intoxication.

In this country few persons venture to eat fungi other than the common edible mushroom (*Agaricus campestris*), but on the Continent, and particularly in France and Italy, a wide variety of edible fungi are consumed regularly, and owing to this variety the risk of making dangerous mistakes is much greater. For example, it is stated that in Italy in 1925 there were seventy deaths due to this form of poisoning. The monograph gives an excellent summary of all aspects of knowledge regarding its subject, and concludes with a bibliography of thirty-three pages. Special mention deserves to be made of the fact that the volume, though it contains twenty-four plates, of which four are coloured, is sold for the very moderate price of sixty francs.

LECTURES ON MEDICAL HISTORY

These lectures on the history of medicine³ were given between the years 1926 and 1932 at various universities in the United States under the auspices of the Mayo Foundation. They vary in excellence, but are all full of information to those members of the medical profession who are interested in the history of their craft. Incidentally, they contain much that is useful to bibliographers. Colonel Fielding Garrison contributes three lectures which are well worthy of consideration. The last deals with the life and work of Dr. John Shaw Billings, whose father kept a little store on a country road, ran a

¹ Recent Advances in Psychiatry. By H. Devine, O.B.E., M.D. Second edition. London: J. and A. Churchill. 1933. (Pp. 364, 12s. 6d.)

² *Le Poison des Amanites Mortelles*. Par R. Dujarric de la Rivière. Paris: Masson et Cie. 1933. (Pp. 182; 24 plates. 60 fr.)
³ *Lectures on the History of Medicine, 1926-1932*. London: W. B. Saunders Company. 1933. (Pp. 516; illustrated. 25s. net.)

shoemaker's shop, and acted as village postmaster. His only son, at the age of 5, was troubled about predestination—or, as his mother preferred to call it, "foreordination." He became a surgical consultant during the civil war, built up the Surgeon-General's Library at Washington, and originated the *Index Catalogue*, which is the envy of medical bibliographers throughout the world. He was responsible, too, for the successful launching of the Johns Hopkins Hospital at Baltimore, for the staff was chosen on his recommendation; and he occupied himself later in life with organizing the New York Public Library and its great network of branch libraries. It is right that an accurate record of his work should be kept, and it is well done both by Colonel Garrison and by Surgeon-General Merritt W. Ireland in his lecture on the Medical Corps of the United States Army. There are also excellent accounts of Ambrose Paré, by Dr. Francis R. Packard; of Renaissance midwifery, by Dr. Joseph L. Miller; of the discovery of the mammalian ovum, by Dr. George W. Corner; of the first American medical journals, by Dr. John M. Armstrong; and of the first American *Materia Medica*, by Dr. Joseph Miller, who tells of "Joyfull newes out of the new-found Worlde." It was written in Spanish in 1565 by Nicolas Monardes, the learned physician of Seville, and Englished by John Frampton in 1577.

The lecture placed last in the book is an intimate sketch of Rudolf Virchow by Dr. William Bartlett, assistant professor of clinical surgery at Washington University, St. Louis. He was a trusted assistant in Virchow's laboratory during the years 1895-7, when the master was verifying Charcot's explanation of cerebral apoplexy. It was Bartlett's duty to prepare the brains, and to show Virchow the millary aneurysms in the arteria lenticulo-striata. It is only possible to indicate a few of the subjects of the lectures, but all are well worth reading, and the Mayo Foundation more than justifies its existence as a promoter of historical studies.

Notes on Books

The official *Medical Register* for 1934 has just been published.* It appears from the table printed in the introductory pages that 1,543 names were added last year—two less than in 1932. New registrations numbered 809 in England, 388 in Scotland, 179 in Ireland, and 167 on the Colonial and Foreign lists. The total number of names on the *Register* at the end of the year was 56,741, representing an increase of 645. The number of names removed from the *Register* during 1933 was 962, as against 1,112 in the previous year. Of these, 820 were deleted on evidence of death, 136 for failure to comply with the inquiries of the Registrar as to cessation of practice or change of address, and six were struck off under the disciplinary powers conferred by Parliament upon the General Medical Council.

Volume liii of the *Transactions of the Ophthalmological Society of the United Kingdom*† contains the communications brought before the society in the session 1932-3; the papers read at the Oxford Ophthalmological Congress in 1933, including the Doyne Memorial Lecture; and the transactions of the North of England and Irish Ophthalmological Societies. This survey of outstanding work during the year is arranged on the usual lines. After the president's speech at the annual congress last May comes the record of a valuable discussion on hereditary eye diseases, three papers on lens diseases, and a report of two cases of carcinoma of the lachrymal sac. Three contributions on retinal diseases, two on neurology, four on radium and ultra-violet therapy, and some miscellaneous articles complete the reporting of the Ophthalmological Society of the United Kingdom. The Doyne Memorial

Lecture last year dealt with investigations on the "aftermath" of cases of intraocular foreign body, and other subjects considered at the Oxford Ophthalmological Congress included gonioscopy, the constitutional factor in diseases of the eye, and diathermy in ophthalmology. The affiliated societies' reports occupy the last sixty pages of the book, and consist largely of clinical notes.

The modern American method of getting together a large association to study a wide subject, appointing a number of committees, each with several directors, to deal with different aspects of it, sending out questionnaires to all sorts of people who may be presumed to be interested in it, and tabulating conclusions, with somewhat elaborate statistics and formulation, in a series of publications, is well exemplified by No. 5 of the School Health Research Monographs, issued by the American Child Health Association.‡ Here, as seems commonly to be the case following on such methods, the main conclusions reached are similar to those already established in this country by a much more modest procedure, though results here would seem to be definitely more favourable. These conclusions are not unimportant, as far as they go, but they seem hardly commensurate with the machinery elaborated and the trouble taken. They are: (1) that teachers have knowledge of only a small proportion of cases that are in need of medical attention; (2) that the proportion is higher where the teacher and school nurse or home visitor act in conjunction; (3) that much of the work of history recording and measurement is best done by the teacher or nurse; (4) that both teacher and nurse require more knowledge and instruction.

For the seventh edition of his *Handbook of Medical Jurisprudence and Toxicology*§ Dr. W. A. BREND has overhauled the letterpress and statistical material. The three recent statutes that have called for most revision of this popular little volume are the Mental Treatment Act of 1930, the Dangerous Drugs Act of 1932, and the Pharmacy and Poisons Act of 1933.

Dr. SIGWALD has written a brochure¶ on the use of sugars, chiefly glucose, in a series of booklets on new therapies (*thérapeutiques nouvelles*). He mentions most of its uses, from its obvious value in hypoglycaemia to its problematical use in tetanus and tubercle. Indeed, he refers to most conditions in which it has ever been tried, and leaves us with no critical opinion as to its possible advantages. The booklet is flimsy, and is weighted neither with a theoretical basis nor with practical facts. It is also unsatisfactory to find many names quoted as responsible for unexpected facts without mention of any published references.

Messrs. George Allen and Unwin, Ltd., are publishing a cheaper edition of Professor Pavlov's *Lectures on Conditioned Reflexes*, translated by Dr. W. Horsley Gantt in collaboration with Dr. G. Volborth, with an introduction by Dr. Walter B. Cannon. The original English translation of this important work was discussed in a leading article in our issue of May 25th, 1929. For the new edition (price 12s. 6d.) the book has not been abridged in any way, and it is illustrated as before.

The report of the joint conference of the National Institute for the Deaf and the Counties Associations for the Deaf, held last December, has now been published, and copies may be obtained from the National Institute's office at 2, Bloomsbury Street, W.C.1 (price 2s. 6d., post free). Subjects discussed in it include the report of the late Dr. Eichholz on the deaf, dumb, and deafened; Circulars 1337 and 1337a of the Ministry of Health; the appointment of a permanent advisory committee on the welfare of the deaf; the need for special legislation in connexion with deafness; and the place of the Counties Associations for the Deaf in the national scheme of welfare work for the deaf.

THE HEALTH OF THE NAVY

REPORT FOR 1932

The statistical report of the health of the Royal Navy for the year 1932¹ is divided into three sections: a general summary of the statistical information; remarks on certain diseases as they affect the total Force and the various stations; and articles on hygiene, pathology, surgery, medicine, and dentistry. For comparison, the average figures for the five years 1927-31 have been inserted, and the figures for 1932 are also compared with those of the preceding year. The total number of cases of disease and injury entered on the sick list was 39,284, an increase of 6.12 per 1,000 in comparison with the five-year average, but a decrease of 19.82 on the figure for 1931. The average number of sick men daily was 1,624.76, being 0.82 less than in 1931, and 0.54 below the five-year average. The total number of days' sickness on board and in hospital was 594,665, which represents an average loss of service of 7.14. The total number invalided was 1,266, a decrease of 1.77 as compared with the five-year average. Many of these were men temporarily invalided from foreign stations, and able eventually to rejoin the active Force. The total number finally invalided—denoting the "waste" of the Service during the year—was 1,013, a ratio of 12.16 per 1,000. Of the 1,266 invalidings, disease-accounted for 1,166. The total number of deaths was 268, a ratio of 3.21 per 1,000, representing slight increases on the 1931 figure and the five-year average. Of this number 131 were due to disease and 137 to injury.

DISEASES AND INJURIES

Four cases of typhoid fever and eight of paratyphoid occurred during the year; there were forty-five cases of dysentery, ten being relapses, and none fatal. In only one of the typhoid cases was a history obtained pointing to infection by food or drink. One patient appeared to have been infected by a friend who lived in a street in Chatham where several cases of typhoid fever occurred during the summer. Of the eight paratyphoid cases, four were recorded by the Mediterranean Station, one by the America and West Indies Station, two by the Home Station, and one by the China Station. The incidence of malaria fell, there being 255 cases in 1932 as compared with 279 in 1931. The China Station reported 100 cases; in fifty-three of these the infection was contracted in or near Hong-Kong. In Africa there were forty-nine cases; Port Harcourt and Fernando Po are considered the principal centres of infection. Opinions differ in West Africa as to the prophylactic value of quinine, but there is some ground for believing that the onset of an attack is thereby delayed, and that cases in which the disease eventually develops respond more readily to treatment. In H.M.S. *Delphinium* all the ratings received 5 grains of quinine in solution on five days a week, and 10 grains on two days a week; in forty selected cases 1/6 grain of plasmoquine simplex was combined with this medication. No fresh infections occurred in this sloop. The opinion is expressed in the report that the anti-malarial campaign organized by the Naval authorities must contribute in no small measure to the low incidence of cases on a station such as this, where malaria is so prevalent. The disease is endemic within the limits of the East Indies Station, but in 1932 there were only thirty-eight cases, whereas in 1929 the figure was 200.

There were 792 cases of influenza, as compared with 2,213 in 1931. The incidence of acute meningococcal infections also fell; the mortality rate was lower and the recovery rate higher. Good results were obtained by frequent lumbar puncture combined with rectal hypotonic glucose solution. Lumbar puncture and the intrathecal injection of serum were performed twice a day in the early stages, maximal quantities of fluid being given by mouth and rectum. After the first four days it was usually possible to perform thecal drainage once a day, and to continue the injection of serum until the cerebro-spinal fluid became clear. If the patient showed toxic signs, such as a rash, intravenous serum was given daily.

¹ H.M. Stationery Office, 1934. (2s. 6d. net.)

Doses up to 40 c.cm. were tolerated. Pulmonary tuberculosis was responsible for 206 cases, as compared with 179 in 1931, most coming from the Home Station and the Mediterranean. There were twenty-four cases of non-pulmonary tuberculosis. In the previous histories of these 230 cases of tuberculosis a definite family infection was traced in eleven; seventy-five patients had seen tropical service of varying periods during the previous five years, five had had malaria, and in fifty cases there was a medical history of predisposing diseases, such as repeated catarrh, bronchitis, and pleurisy. Three cases of undulant fever were reported from the Home Station and twelve from the Mediterranean. During the summer of 1932 the disease was more than usually prevalent in Malta, but the source of infection could not be traced in any instance. The question of pasteurization of goats' milk is being considered. The number of fresh venereal infections fell again in 1932, there being 4,638 as compared with 4,962 in the previous year. Gonococcal infection was lessened, by 237 cases, syphilis (first record) by twenty cases, and chancroid by sixty-seven. Diseases of the respiratory system fell by 2,232 as compared with 1931, the total being 7,256; the majority were catarrhs. The figure for general injuries was 328, as compared with 235 in 1931; this figure includes cases of multiple injuries, burns, and scalds, heat-stroke, drowning, suffocation, and compressed-air disease.

SPECIAL DEPARTMENTS.

Mention is again made of the occasional evidence of contamination of Plymouth water by gulls. The introduction in 1930 of Dick tests and active immunization against scarlet fever in the boys' training establishment *St. Vincent* has proved encouraging: 90 cases per 1,000 in 1928, and only 4.8 in 1932. Further research on undulant fever has been conducted at Malta, where Huddleston's (1928) haemagglutination test has proved reliable as a bedside aid to the diagnosis of Brucella infections, and a modified method of preparing the antigen for it has been designed. Examination of the melitin test showed that the reaction seldom became positive until the later stages of the disease, and was therefore useless in the diagnosis of acute cases. It was found, also, that when the reaction had once become positive it remained so for many years. The test proved useful in distinguishing between old and very early cases, and might be the only means of recognizing certain chronic febrile cases. It is suggested, further, that since *melitensis* cases seldom show a positive melitin reaction until they begin to improve, this test may have a prognostic significance. If it is performed during the early stages of the disease and a severe constitutional reaction follows, although the local reaction remains negative, this is very strong evidence in favour of the diagnosis of undulant fever.

Further research into the effect of active prophylactic immunization against diphtheria of the boys at Greenwich Hospital School was undertaken at the Royal Naval Medical School. During the autumn term there were eighteen cases of diphtheria, and, finding that some of these patients had lost their immunity and become Schick-positive, the whole school was retested, forty-eight out of 734 boys being found thus to be Schick-positive in some degree. Of the forty-eight nine had joined the school naturally immune, while the remaining thirty-nine had been immunized by inoculation subsequent to joining. It was confirmed that the stimulus provided by the Schick test had sufficed to restore the Schick immunity of all but one of the nine boys who had joined the school naturally immune, but of the thirty-nine artificially immunized only four responded to the stimulus of the test to a degree sufficient to raise the circulatory antitoxin above the Schick level. A small outbreak of diphtheria occurred in the last quarter of 1932, but only four of the eighteen cases were clinically recognizable, and three of these had not had time to develop immunity. The infective agent was the C diphtheria "gravis type"—previously known as the cause of the severe and intractable cases of the Leeds epidemic three years ago. The school epidemic was so mild, on the contrary, that in several instances no antitoxin treatment was required. For new boys joining the school during 1932 the Moloney, or Canadian, intradermic test was used to eliminate those likely to give undue reactions after prophylactic doses of toxoid. Boys who were Moloney-negative and Schick-positive were immunized with toxoid without unduly

severe reactions. Boys who were positive to both tests were immunized with toxin-antitoxin flocules.

A follow-up system for contrasting the end-results of the different types of operation for inguinal hernia has been instituted, but it is as yet too early to define the relative merits. In the acute stage of gonorrhoea hexamine has come back into favour at Chatham as compared with alkalis. A vaccine containing strains of gonococci and secondary organisms appears to have lessened complications. This vaccine proved useful also in chronic cases and metastatic sequels. The improvement in the dental health recorded in 1931 was continued in 1932, the volume of prophylactic and conservative treatment increased, and fewer cases needed root treatment.

MEDICAL PROGRESS IN FIJI

The earliest records of British colonization in the islands of the Western Pacific show that administrative and medical authorities have always agreed that the best way of bringing up-to-date medical aid to the native inhabitants is to train native medical practitioners. A native medical school has been in existence for more than fifty years at Suva in the island of Vitilevu, and, during the last six, special efforts have been made in the new Central Medical School to provide a more adequate and practical scheme of instruction. The establishment of this new school for native students from the various island administrations arose out of the co-operation of the Rockefeller Foundation in a survey of health problems, and already many native practitioners are at work in islands where before there was but little medical treatment. Isolated places are now being helped in this way, and a determined campaign against ignorance and superstition is being carried on. The local Branch of the British Medical Association has taken great interest in the school, presenting to it equipment of different kinds and awarding a gold medal in surgery. It holds its clinical meetings in the school buildings. A journal of practical medicine has been brought into being; the first issue of *The Native Medical Practitioner* appeared in November, 1930; the second in April, 1931; the third in March, 1932; and the fourth in February, 1933. Fijian medical practitioners are contributing to its columns in increasing numbers, and its value to them in keeping their knowledge up to date is obvious. Its inception was largely due to Dr. T. Clunie, honorary secretary of the Fiji Branch of the B.M.A. Mainly devoted to practical clinical topics relating to diagnosis and treatment, it serves to instruct and encourage native doctors in very isolated situations, and to link them together and with their school. At the beginning of 1932 there were forty students in residence, this being the maximum number the dormitories could accommodate; they represented eight different native groups, varying much in such respects as amenability to discipline, ability to learn, and readiness to accept responsibility. The course lasts now for four years; there is an entrance examination, and a certificate is awarded when the final examinations have been passed.

THE COLONIAL WAR MEMORIAL HOSPITAL

A milestone in the history of Fijian medicine was reached at the end of 1923 with the opening of this institution. In his annual medical and health report for 1932 Dr. A. H. B. Pearce, chief medical officer to the Fiji Legislative Council, states that this large and well-equipped hospital is being increasingly patronized by Europeans, many of whom in the past would have gone for treatment to New Zealand or Sydney. The work was much heavier than in the preceding year—every bed occupied and a long waiting list. The number of in-patients treated was 2,345, and of out-patients 20,049, as compared with 2,303 and 14,041 for the previous year. In the in-patient theatre 635 operations were performed, and 590 minor operations in the out-patient theatre. The medical superintendent, Dr. T. Clunie, reports

that the third- and fourth-year students from the Central Medical School act as dressers and male nurses, in addition to undergoing training periods in the dispensary, eye department, and post-mortem room. Post-graduate courses are conducted by local practitioners of at least five years' standing. Clinical meetings have been arranged from time to time at the medical school. During the year under review the x-ray department was reorganized, and such procedures as intravenous pyelography and cholecystography were introduced. Attempts are being made to build up a blood transfusion service, and a study of blood groups in the Pacific is proceeding.

CHILD WELFARE WORK

Since the inauguration of a scheme of child welfare work in 1927 in the province of Tailevu, this activity has rapidly extended to nearly every district in Fiji. At the beginning of 1932 there were six qualified European child welfare nurses working at centres, while Fijian women's committees were operating in districts where there were no centres. The natives are showing a growing appreciation of this work, and in several provinces the wives of chiefs and officials are taking an active interest in it. In a native suburb of the town of Suva, where there is a considerable Fijian population, a committee of women has arranged for the daily inspection of children, regular visits being paid to the homes with the object of improving sanitary conditions. Monthly meetings are held by the assistant secretary for native affairs and the medical officer of health. In connexion with this work an ante-natal clinic has been opened at the Colonial War Memorial Hospital, with sessions at fortnightly intervals. Its work is limited to Fijian natives, but it is hoped to extend these services to Indians should application be made. Dr. Clunie is convinced that such a clinic could be of immense value in saving many lives annually, as well as in avoiding much ill-health for mothers and prospective mothers.

GENERAL HEALTH MEASURES

The mass inoculation of the population with T.A.B. vaccine is being continued, and 15,000 injections were given in 1932. The incidence of enteric fever is steadily decreasing, as also is that of amoebic dysentery, which had been previously both widespread and severe. The port health authorities are using every means to prevent the introduction of the anopheles mosquito into the Colony, very strict regulations being enforced in the case of ships arriving from malarial ports. The bad sanitary conditions reported in 1930 in Suva have now been remedied, but it is held that a system of house-to-house inspection is still necessary if further needed improvements are to be effected in water supply, surface drainage, and disposal of house refuse.

CONTROL OF LEPROSY

The Central Leper Hospital at Makogai reports that the number of cases in need of treatment is increasing. Dr. C. J. Austin, its medical superintendent, is convinced that there are still many undetected cases. He remarks that in such a centre as Makogai, where there are patients of so many different races, it should be a matter of inquiry how far the racial factor affects the degree of resistance to infection and of response to treatment. Careful examination indicated the Indians as being more liable to the cutaneous than to the neural type, while in the Fijians the liability was reversed. Indians responded more readily to treatment, but this apparent anomaly is probably due in part to the Indians taking greater care of themselves, and being more willing to undergo treatment so as to rejoin their relatives outside hospital. The Fijians, on the other hand, find themselves comfortable, have no particular fear of the disease, and do not exert themselves to get well. All patients are encouraged to take chaulmoogra oil by mouth to the limit of tolerance, 0.5 per cent. iodine being added to render the drug more palatable. The iodized (0.5 per cent.) ethyl esters of hydnocarpus have been found to be the least irritating and the most popular. In controlling developed reactions the three most useful drugs are held to be ephedrine by mouth, antimony and sodium tartrate intravenously, and the ethyl esters of calophyllum (dilo) intramuscularly.

AN INVESTIGATION OF MATERNAL MORTALITY

An inquiry undertaken by the New York Academy of Medicine into the maternal mortality of that city has yielded results of great interest and importance.¹ The director of this investigation, Dr. Ransom S. Hooker, after referring to the failure of previous inquiries in New York to achieve results, describes the plan which was eventually evolved by the Public Health Relations Committee of the Academy, in consultation with an Obstetrical Advisory Committee, consisting of men of great experience and distinction. They decided to conduct a continuous inquiry, limited to New York City, over a period of three years, weekly reports of all maternal deaths being received in order that the investigation should run concurrently with the deaths, and the inquiries be made while the circumstances were still fresh in the minds of the attendants. The task of collecting the material was entrusted to two medical women, who personally sought all the information, with the assistance in respect of midwives' cases of a registered nurse-midwife. All persons who had been in attendance upon the patients at any time were interviewed. The material thus obtained was reviewed monthly by the Obstetrical Advisory Committee in consultation with the investigators themselves. The alternative method of eliciting facts by questionnaire had been tried before and shown to be unreliable. The authors believe that their method of direct personal inquiry by selected investigators is much more likely to yield accurate data, an opinion in which all who have had experience of the answers received to a questionnaire will concur. The data thus obtained were analysed, classified, and correlated by the Advisory Committee before conclusions were drawn. In all 2,041 maternal deaths were passed in review.

The maternal mortality rate for New York City (5.76 per 1,000 in 1931) is admittedly high, though considerably below that for the whole registration area of the United States, which was 6.6 per 1,000 in the same year. In the cosmopolitan character of its population, and in the existence of large slum areas, the conditions do not differ materially from those of London.² The presence, however, of a negro population, estimated at 248,000, forms a complication of which we have no experience in this country. During the period covered by the inquiry the maternal mortality rate was 11.5 per 1,000 for negro women as against 5.5 per 1,000 for whites. The high maternal mortality rate prevalent among negroes is widespread in the

United States, and formed a subject of comment in a report of the White House Conference reviewed in these columns on January 13th (p. 69). The first concrete result which emerged from the inquiry was that the returns published by the New York State Department of Health considerably underestimated the true extent of the maternal mortality. The investigations of the committee made it possible to check the published figures, with the result that the maternal mortality rate for 1931 was shown to be, not 5.76, but 6.12, and the rate for septicaemia alone was shown to be, not 1.58 as published, but 2.36 per 1,000 births. The cases judged to have been wrongly certified were not reported in all instances by independent practitioners; some were hospital cases, for which, however, expert obstetric diagnosis was not available. It is not suggested that underestimation was wilful, but the extent of the inaccuracies, amounting in respect of septicaemia to nearly 50 per cent., is certainly surprising.

The committee determined that one of its most important objectives should be to pick out the deaths which could have been avoided, and throughout the report a classification of deaths as "preventable" or "non-preventable" has been followed. The principles upon which classification was based are not susceptible of brief statement, but they emerge fairly well from the illustrative cases recorded in the report. In the result 65.8 per cent. of the total deaths were judged to have been "preventable"; in the case of deaths from septicaemia this figure rises to 75.1 per cent. Out of forty-seven deaths from therapeutic abortion two-thirds were held to have been preventable, and out of 117 deaths following post-partum haemorrhage no fewer than ninety-three were thus regarded. There were 310 deaths after Caesarean section, and of these 246 were judged to have been "preventable." In reading the comments on these cases one cannot escape the reflection that after all preventability is relative, and should be estimated with regard to the degree of obstetric skill which the average doctor and midwife may fairly be assumed to possess, together with the facilities which are available for obtaining expert assistance and advice. These considerations have clearly been in the minds of the committee, for it is not suggested that fatalities classed as preventable necessarily carry an implication of negligence or of incompetence. The committee has endeavoured to push the question of preventability a stage further in allocating responsibility to the physician, the midwife, or the hospital in the case of certain groups of maternal deaths. It appears probable, however, that in a proportion of cases ineffective co-operation between the different elements of the maternity service was mainly responsible. To the lack of co-operation between physicians and midwives the committee makes regretful reference. A remarkable feature, which illustrates this point, is that out of 898 deaths from causes other than sepsis, 259 patients died undelivered—that is, a proportion of 28.8 per cent. There were in all 231

¹ *Maternal Mortality in New York City, 1930-1932.* By the New York Academy of Medicine Committee on Public Health Relations. London: H. Milford, Oxford University Press. (8s. 6d. net.)

² The comparable figure for the Administrative County of London was 3.68.

patients who died from albuminuria and eclampsia, and of these ninety-one died undelivered—a proportion of 39 per cent. In view of the abundant hospital provision available for midwifery in New York, this regrettable feature can only be attributed to defective organization.

During the period of the inquiry 70.7 per cent. of all confinements occurred in hospital, a proportion very much higher than could be found in any English city. In all countries operative deliveries are relatively more frequent in hospital than in domiciliary practice, for reasons which are well recognized. The calculation made by the committee from various data is that while in hospital operative deliveries constituted 24.3 per cent., the proportion for the whole city reached the astonishingly high figure of 20 per cent. Upon this estimate is based the further estimate that the over-all mortality rate was 10.5 per cent. for operative as against 2 per cent. for spontaneous deliveries. It is, however, open to question whether any useful purpose is served by setting up a comparison between spontaneous deliveries, on the one hand, and, on the other, a group of widely differing operative procedures—for example, low forceps and Caesarean section. There can be no true basis for comparison between them. The rapidly increasing frequency with which Caesarean section was performed is the subject of stern comment in the report. At the New York Lying-in Hospital this operation was performed in 4.98 per cent. of all private cases, and in 3.28 per cent. of all cases in the open wards. Many of the operations were done "on request." The data required for calculating the mortality rate for all Caesarean operations were not available, but it is ominous that 50 per cent. of the reported deaths were due to infection. The conclusion of the committee is that "the indications for Caesarean section need restatement and limitation to really valid causes"; and, further, that "only those with adequate training in abdominal surgery should be considered suitable operators."

The committee regarded it as important to consider the "type of medical attendant" in relation to mortality, and the details were actually obtained for all the 115,621 births which occurred in 1931. The great majority could be classified as obstetricians, general practitioners, surgeons, or midwives. The remainder formed a heterogeneous collection of thirteen different kinds of specialist, of whom the paediatricians were the most in favour, and psychiatrists the least. The midwives come out best, with a mortality rate of 1.4 per 1,000, the surgeons being far behind them at 9.9 per 1,000, due largely, it is believed, to the predilection shown by them for Caesarean section. The veil is not lifted upon the results obtained by the group of "miscellanies." It would appear that re-education of the New York public in the exercise of its right of free choice of doctor is one of the urgent needs of the moment. The American attitude towards midwives is changing rapidly. The report declares that "the midwife's results are as good as those obtained by the

physician . . . under comparable circumstances and for comparable cases." In view of these results the opinion is expressed that the relative advantages of hospital and domiciliary midwifery in New York City demand reconsideration. We welcome this approach to the position which has so long been held in this country. The report closes with a chapter of conclusions which shirk no issue and are characterized by a high courage and an entire frankness which cannot be too warmly commended. And it must be admitted that our New York colleagues have shown us a better way of studying maternal mortality in the mass than we have been able to evolve for ourselves.

AUTOPHARMACOLOGY

Sir Henry Dale chose the title "Progress in Auto-pharmacology" for the Dohme Memorial Lectures which he delivered last year in Baltimore. These lectures have now been published,¹ and they give an interesting review of an important new development in physiology and pharmacology. Claude Bernard discovered that the liver supplied sugar to the blood by breaking down its glycogen, and this process he named "internal secretion." He realized the dominant importance of the composition of the fluids bathing the body cells (*milieu interne*), and conceived the general idea of this medium being modified in innumerable ways by the activity of organs. The sensational discoveries of endocrinology diverted interest from this wide conception, and focused attention on the activities of the small glands which specialize in the internal secretions. It has now become clear that the vital functions, and in particular the circulation, are largely regulated by a whole range of substances formed by tissues which are not so specialized. The regulation of respiration by carbon dioxide tension is a classical illustration of this process, but in recent years many new examples have been found.

The investigations of Dale and his collaborators into the nature of the active principles of ergot revealed the presence of the two interesting substances, histamine and acetylcholine. For many years these were looked upon as pharmacological curiosities, but it was gradually realized that they were of great physiological significance. The importance of histamine was established by two discoveries: first, that large doses resulted in a condition very similar to that of shock, and, secondly, that traces of histamine occurred in certain organs. Magnus and his school demonstrated that the activity of the gut was regulated by the presence of acetylcholine, whilst Loewi showed in 1920 that the vagus nerve acted on the heart by liberation of acetylcholine. This work provided a new conception of the mode of action of autonomic nerves, and also established the fundamental physiological importance of acetylcholine. In recent years a series of other natural constituents of body tissues have been identified and found to produce powerful pharmacological actions. Adenosine

¹ Bull. Johns Hopkins Hosp., 1933, liii, 297.

phosphate was shown by Drury and Szent-Györgyi to bring about a powerful vaso-dilator action, and also to cause heart-block. In addition, a number of other vaso-dilator and vaso-constrictor substances have been partially identified. Unfortunately, work in this field is of quite exceptional difficulty, for the active principles are numerous, they occur together as a rule, and are easily inactivated by chemical treatment. For these reasons it usually takes many years to determine with certainty the identity of an active principle present in organ extracts, and after this has been achieved it may prove an even longer task to decide the probable role of the substance in normal physiological processes. Often the evidence available is so contradictory that it does not even indicate probabilities to anyone who has not extensive experience of the technique involved.

Sir Henry Dale has presented in his lectures a masterly account of an intricate and confused subject. Discoveries in this field have already modified our fundamental physiological conceptions and have been of some service in therapeutics. It seems probable that the subject will be of far greater importance in the future. Sir Henry Dale summarizes the present position in the following words: "... it already seems possible to state that the whole of the control of the activity, not only of the blood vessels, but of all the involuntary muscle and gland cells in the body, is effected by a series of chemical, pharmacodynamic agents. These may be liberated by impulses in sympathetic or parasympathetic nerve fibres, including with the latter the axon-branches of sensory fibres to blood vessels; or they may be formed in endocrine organs, and distributed by the blood to produce their effects simultaneously on all cells responsive to their action; or, finally, they may be widely distributed in tissues having no special endocrine function, and their liberation to produce local pharmacodynamic effects may be independent of any nervous control. Already we can write whole chapters of this story in terms of exact chemistry, and there can be little doubt that others will follow."

WATER SUPPLIES

The long-continued drought is over for the time being, but it will need much more rain than we have already had this month to remove anxiety about next summer's water supply. Most of the urban authorities have withstood remarkably well the strain of an exceptional period of dry weather, but many rural areas have suffered hardship. On February 21st the Ministry of Health issued a circular and memorandum to local authorities and waterworks companies, calling upon them to scrutinize their position with an eye not merely to the needs of the moment but to possible difficulty in the future. "They should have plans for economizing consumption and for augmenting supplies ready to put into operation if the drought continues and further measures become necessary." It was pointed out that inconvenience to the consumer is a less evil than the grave shortage and more drastic restrictions which it sets out to avert. In a speech last Friday the Minister said that the recent rain was helping the dried-up rural areas, but had not made

much difference yet to the water situation in the towns, and the outlook for the summer was still one of difficulty. Among the matters on which the Ministry's Memorandum of February 21st (178 W) gave guidance was the risk of pollution. "Wherever the purity of the water is threatened special means of purification should be undertaken. The readiest of these is chlorination. Chlorination should be employed only under expert supervision, and with the precautions necessary to secure that the process is properly and efficiently carried out." A further Memorandum (179 W) has now been issued on the treatment of water with chlorine as a means of rapid and effective sterilization. The great thing about chlorination is that if it is adequately carried out water which could not in the ordinary way be used without risk to health can be safely brought into service, thus making available new sources of supply in time of shortage. While the welcome showers of the past two or three weeks have eased the situation, only a continuance of wet weather can make up for the abnormally low rainfall since March, 1933. So far as public health is concerned, it has to be kept in mind that where surface gathering grounds are subjected to heavy rains following a drought a larger proportion of impurities may find its way into the reservoirs, and so call for special methods of purification.

DINITROPHENOL FOR REDUCING WEIGHT

The recent death of a young professional dancer from poisoning by a nitrophenol compound (dekrysil) has given publicity to the dangers of taking allied compounds for the purpose of "slimming," and we would draw the attention of readers to an article by Dr. D. M. Dunlop in our current issue (p. 524), in which a useful summary is given of present knowledge on these drugs, with the results of experimental work. It has been known for some time that the nitrophenols are powerful stimulators of metabolism, causing a marked increase in oxygen consumption. A few years ago workers in Heymans's laboratory demonstrated the potent effect of dinitrophenol in raising the basal metabolic rate: it was found that doses of about 0.1 gram could cause an increase of about 50 per cent. Dodds and Pope have shown¹ that another compound, dinitro-*o*-cresol, is about five times as potent as dinitrophenol. Recent work in America² indicates that dinitrophenol acts by stimulating the metabolic activity of the cells by increasing their oxygen consumption, and that its action is independent of nervous or glandular activity. Dr. Dunlop's conclusion that the increased metabolism is mainly at the expense of fat confirms the observation of other workers. The fact that administration of dinitrophenol is accompanied by no significant change in pulse rate or blood pressure was thought to give this drug an advantage over thyroid in cases in which reduction of weight is considered to be necessary. The danger of this, however, is that the practising physician is deprived of these clinical means of observing the effect of the drug, which are of great value in thyroid medication; and, as Dodds and Robertson³ point out, it would appear that the action of the drug should be checked by determination of the basal metabolic rate: estimation of this

¹ *Lancet*, 1933, ii, 353.

² *Journ. Amer. Med. Assoc.*, 1933, ci, 2122.

³ *Lancet*, 1933, ii, 1137.

by Read's formula would of course be unreliable. Dinitrophenol is no substitute for thyroid in myxoedematous states. If the drug is pushed too far it causes a rise of temperature which may end in a fatal hyperpyrexia, and it seems that the margin between the febrile and the fatal dose is small. Dodds observed that sweating, lethargy, headache, loss of appetite, and a greenish-yellow conjunctiva appeared as toxic effects if the basal metabolic rate exceeded +50 after administration of dinitro-*o*-cresol, and Wassermann and Goldsmith,¹ who report one fatality in eighteen cases treated by dinitrophenol, also noticed a yellowish discoloration of the skin and conjunctiva, remarking that this drug is "unpredictably toxic" to some patients. The dangers of drugs of this potency are obvious, but clinical evidence suggests that they can be safely employed for short periods provided they are given under the strictest medical supervision. The grave risk incurred by uncontrolled self-medication has been brought home to the public in a tragic manner, and it would appear desirable that more extensive trial of these drugs should be made under institutional conditions before they are widely used in private practice. Dr. Dunlop points out that, considering the great increase in general metabolism, the loss of weight following the employment of dinitrophenol is disappointingly small, and he sounds a note of caution when he says: "It has yet to be demonstrated that they are as safe and effective for weight reduction in human beings as other methods in common use."

PHYSICAL TRAINING IN SCHOOLS

Not many medical men realize the great debt that they and the whole community owe to the Board of Education for its enterprise and skill in the organization and development of physical training in the schools of the country. Fifty years ago physical training was an unsatisfactory affair of dumb-bells, strained muscles, and violent stamping, carried on indoors in heavy clothes. The official handbook² recently produced by the Board of Education shows the great changes that have taken place. This should be bought and studied carefully by everyone who is interested in the physical training of children, for it is one of the most practical and detailed textbooks that have appeared, and its methods are as sensible and effective as careful research into scientific physical training can make them. It is mainly concerned with children between the ages of 5 and 11, but it includes a section dealing with an extension of the training to ensure continuity with the older groups. The Board proposes to issue separate syllabuses for senior boys and girls between 11 and 15. After discussing the fundamental principles that underlie all physical education, and teaching methods suitable for children in general, it gives some splendid advice on organizing games, dancing, and swimming, and a series of exercises for every part of the body, illustrated with attractive line drawings and photographs. The instructions are so detailed that the teacher of very moderate inventiveness will be able to keep his or her class amused on a whole succession of cold days with only the slightest forethought. The general remarks on posture show more than anything

the immense strides physical education has made, and the sympathetic intelligence with which it is taught. A section which has a counterpart in hardly any manual of the kind is that on training leaders, one of the most vital duties of every teacher. It is enough to say, by way of praise, that the book will make all middle-aged people envious of the school children of to-day, and that if young officers had possessed this book during their struggles to train recruits in the war, it would have made the difference to them between chronic anxiety and effortless achievement.

WORK OF A RHEUMATISM CLINIC

The work of the British Red Cross Society's Clinic for Rheumatism in Peto Place, Regent's Park, continued to expand in 1933. The extent of routine investigation and the range of treatment have widened, while several researches are being made in the attempt to elucidate some of the problems presented by the various rheumatic diseases. During the year 2,719 new patients were seen in the general out-patient department, and 644 in the private department. The average number of attendances in the former was 25.95, while in the latter the average was only 12.9. This striking difference has been attributed to the generally less advanced rheumatic condition of the private patient seeking treatment, and to the greater proportion of those attending the general out-patient department who are employed in heavy manual, exposed, or outdoor occupations. Another possible factor is that a number of persons of limited means cease their attendance on the private floor after obtaining a certain measure of relief, on account of the financial strain entailed by protracted treatment and the time and distance involved in coming to the clinic. The medical board points out that although the importance of referring early cases of rheumatism for treatment is gradually becoming more and more appreciated, advanced cases are still sent to the clinic. A large number of such patients who might have had a reasonable prospect of returning to their normal work if treatment had been begun earlier are thus condemned to a life of more or less permanent invalidism, and any treatment given is, at the best, only palliative. Emphasis is therefore laid on the need for attending as soon as symptoms indicative of rheumatism have made their appearance. Reference is again made to the number of grave pathological non-rheumatic conditions sent up for investigation and treatment. The prestige of the clinic depends to a large extent on the fact that it has the facilities available for detailed examination and investigation of an obscure and difficult case in order to make a correct diagnosis, and the figures quoted in the report show the need for making a thorough routine examination of every patient coming for consultation. In attempting to assess the results of treatment of the rheumatic diseases all figures must be accepted with a certain amount of reserve, since so many factors modify any interpretation and deduction based on statistics. Bearing all these factors in mind, the following figures represent the results of the investigation into the effect of treatment on patients discharged from the Red Cross Clinic. During last year 957 men and 1,615 women were discharged, but of these 196 men and 419 women did not complete treatment, and 43 men and 54 women were discharged on account of intercurrent disease.

¹ Journ. Amer. Med. Assoc., 1934, cii, 523

² Syllabus of Physical Training for Schools, 1933. London: H.M. Stationery Office, 1933. (Pp. 352. 1s. 6d. net.)

The results of treatment expressed in percentages of the remaining 718 men and 1,142 women are as follows:

	Men	Women	Men and Women
Cured	26.0	13.2	18.3
Considerably improved	25.9	27.6	26.8
Definitely improved	32.5	36.6	35.0
Slightly improved	2.2	3.8	3.2
Unchanged	12.1	17.8	15.6
Worse	1.3	1.0	1.1

Thus the percentage of men discharged as cured is almost double that of the women. Almost the same results were experienced in 1932, when the explanation advanced was that this was due to the fact that a larger percentage of men attending the clinic were suffering from some non-articular form of rheumatism, and that a man, being usually the chief wage-earner of the family, is more likely to come for treatment when his rheumatism is in a less advanced stage, owing to the serious economic results of prolonged disability. The proportion of patients whose condition was either unchanged or worse is definitely higher in the case of women. The results of treatment show that a greater percentage of both men and women derived benefit from their attendance at the clinic in 1933 than in 1932, and this may possibly be due to the fact that patients are now presenting themselves when their rheumatism is less advanced. The extent of the collaboration of the physician with the different special departments is referred to in some detail in the report, because it is believed that collective work upon the problem of efficient treatment will yield valuable results.

ST. DUNSTAN'S.

The nineteenth anniversary of the foundation of St. Dunstan's, the organization that looks after all blinded ex-Servicemen from the British Empire, falls on Monday next. It took its name from Mr. Otto Kahn's house, St. Dunstan's, in the Outer Circle of Regent's Park, lent for the purpose, and there, on March 26th, 1915, the late Sir Arthur Pearson really began the work with sixteen war-blinded patients. Before that a few cases had been treated at a house in the Bayswater Road, but with the removal to St. Dunstan's the work of the organization may be said to have begun. The first case of war-blindness was that of a Belgian soldier, whose plight came to the knowledge of Sir Arthur Pearson at about the same time as he heard of that of three British soldiers, whereupon he conceived the idea of starting a hostel to teach blinded soldiers and sailors and airmen to "learn to be blind." By 1918 the numbers had increased to 1,500, and since then they have risen to 2,000. There were twenty-seven new cases during the last recorded period of twelve months. Now St. Dunstan's looks after about 2,000 war-blinded ex-Servicemen and 5,000 of their dependants. As a result of the work of the settlement and after-care department, originally started by Captain Ian Fraser, M.P., now chairman in succession to Sir Arthur Pearson, the great majority of these men are installed in their own homes and carrying on the occupations they have learned since being blinded. In 1920 St. Dunstan's moved to quarters in the Inner Circle of Regent's Park, where its administrative headquarters are still housed. A number of "bed" cases are looked after at St. Dunstan's at Brighton, which is also used as a convalescent and holiday home.

INTERNATIONAL SOCIETY OF SURGERY

The next Congress of the International Society of Surgery will be held in Cairo from December 28th to 31st, 1935, under the presidency of Professor A. von Eiselsberg of Vienna. The subjects selected for discussion are: (1) surgery of the parathyroids; (2) surgery of the lumbar sympathetic; (3) surgery of the colon (cancer excepted); and (4) the surgical complications of bilharziasis. Members of the society who wish to take part in any of the discussions should send their names to the secretary-general, Dr. L. Mayer, 72, Rue de la Loi, Brussels, or to the British delegate, Professor Grey Turner of Newcastle-upon-Tyne. It is hoped that some of the surgeons taking part in the Annual Meeting of the British Medical Association at Melbourne in September, 1935, will be able to attend the Cairo congress on their way home.

BIOLOGICAL ASSAY

The eighth annual report of the Pharmacological Laboratories of the Pharmaceutical Society contains a record of a wide variety of work. It is interesting to note that research workers from all parts of the world have come to the institute in Bloomsbury Square during the past year to study methods of biological assay. This fact is evidence of the increasing importance of these methods, which the laboratories have done so much to advance. One of the most interesting lines of investigation on the pharmacological side is the development by the director, Professor J. H. Burn, of a hypothesis relating asthma to adrenaline deficiency. The nutrition department has evolved various technical improvements in methods of vitamin assay. Biochemical advances are causing rapid changes in this subject, and in this respect it is worthy of note that the antiscorbutic activity of 1 mg. of the pure principle, ascorbic acid, has been estimated at 7.4 units, which is equal to 0.74 c.cm. of lemon juice. The amount of vitamin C needed by a mammal is therefore relatively small, though it is true that this quantity is more than one thousand times as great as the corresponding quantity of calciferol.

HYPOCHONDRIASIS

Few lectures given to a purely professional audience have had wider—or, on the whole, more intelligent—notice in the newspapers than Dr. Robert Hutchison's address on hypochondriasis published in the *British Medical Journal* of March 3rd. Among the many editorials for which it has served, so to speak, as a text may be mentioned particularly a leading article headed "The Return of Fear" in the *Church Times* of March 16th. In this the editor discusses, from the point of view of national and social well-being, "the thesis which this wise physician applies to the conditions of physical health."

We regret to announce the death in Peking, at the age of 49, of Dr. Davidson Black, F.R.S., professor of anatomy at the Peking Union Medical College, whose name is known throughout the world of science in connexion with his work in human palaeontology, and in particular with the discovery five years ago of the fossil *Sinanthropus pekinensis*.

MEDICAL RESEARCH COUNCIL

REPORT FOR 1932-3

In a leading article in the *Journal* of March 10th we drew attention to some of the general features of the Annual Report of the Medical Research Council,¹ and in this and a subsequent issue it is proposed briefly to summarize the accounts therein given of research work carried out under its auspices.

INFLUENZA AND VIRUS DISEASES

In the *Journal* of July 15th, 1933 (p. 115), we commented on the work done on influenza by Laidlaw, Andrewes, and Wilson Smith, who, using the ferret as an experimental animal, came to the conclusion that the primary infective agent in influenza is a filter-passing virus. Discussing this work in its present report, the Council points out that the experimental approach to the problem of influenza had for long been held up, not for lack of material resources, but because no laboratory animal was known to be susceptible to the disease. The brilliant investigation into canine distemper (a disease probably due to a virus) in which it was found that the ferret had a high susceptibility to the disorder, led to the use of this animal for experimental purposes during the influenza epidemic at the beginning of 1933. The fact that ferrets developed a febrile reaction and a nasopharyngeal catarrh after nasal instillation of filtered washings from the nasopharynxes of human beings suffering from influenza, and the serial transmission of the disease from ferret to ferret, from filtered material, strongly pointed to a filter-passing virus as being the primary infective agent. The relation of this virus to that found by Shope in "hog-influenza" has already been remarked upon.² The swine virus produced in the ferret a condition indistinguishable from that caused by the human virus, and the ferret recovered from either infection has an immunity to the other (partial to the swine virus on recovery from the human, and complete for the converse). "At this early stage," the report states, "no claim can be made without cautious reservation as to the need for repeating experiments and of confirming results; and, in any event, the prospect of practical application is still remote."

Work continues on the unit dimensions of viruses, and the correspondence between the measurement of viruses by Dr. Elford's method of differential filtration and those obtained by Mr. Barnard's ultra-violet photomicrographs strengthens the evidence for the identity of the optically demonstrable particles with the virus. Comparative measurements of this kind have been made for the viruses of vaccinia, fowl-pox, ectromelia, canary disease, Borna disease, and vesicular stomatitis of horses and cattle. Dr. Elford's experiments suggest that the diameter of the infective units of the last-mentioned disease is somewhere between 70 and 100 millimicrons (1 millimicron = one millionth of a millimetre). Mr. Barnard has identified minute particles in the fluid from the vesicles in this disease. As such units (70 to 100 millimicrons) must be close to the limit of critical resolution with the shortest ultra-violet wave-length that can be used with present-day optical apparatus, the correspondence of measurements by filtration and by photomicrography has been extended to the lowest limits of detection. The cultivation of viruses under artificial conditions continues to present considerable difficulties. Attempts have been made to grow viruses in cultures of tissues from susceptible animals. Dr. Burnet has been carrying on researches on the classification of bacterio-

phages. Experiments go to show that bacteriophages are independent transmissible agents analogous to the viruses. Their properties have several points of resemblance to those of the visible bacteria, and recent work has strengthened the conception that bacteriophages are infective agents organized into extremely minute particles. The photodynamic inactivation of viruses by means of methylene-blue in the presence of light and free oxygen has been turned to practical account by Drs. Perdrau and Todd, who have used the virus of canine distemper, inactivated in this way, as a vaccine, with the successful immunization of ferrets and dogs.

BACTERIOLOGY
